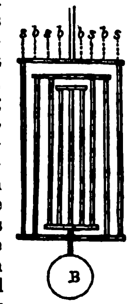
Pendulum-rods, which are usually made of metal, though sometimes of wood, especially in church-clocks, were next found to vary in length by variations of temperature, according to that law of nature by which every body increases in volume or in actual size by heat, and diminishes or contracts by cold. The inevitable consequence of the influence of such variations on the length of the pendulum will at once be seen, from what has been already said, to be an increase of the number of its oscillations in a given time while in cold temperatures, and hence shorter than its mean length, as in winter, or even at night, or in cold situations; and a diminution of them while in warm temperatures, and hence longer, as in summer, or even during the day, or in warm situations: and a pendulum with a metal rod will cause a clock to vary several seconds in a day from such changes alone. To insure, therefore, a still greater accuracy and uniformity in the measurement of time than had previously been obtained, various ingenious but simple devices have been put into practice, wherein the very cause of the inaccuracy has been made subservient to the end desired. And here the talent of the artist Graham again displayed itself, and led the way to every other modification of the primitive *idea*, however dissimilar in detail, and whether applicable to pendulums or balances, to clocks or watches. Indeed, the first method of 'compensation' adopted for pendulums has, with some little improvement, ultimately superseded all its more recent modifications. This method Graham called the *mercurial compensation*, and it consists simply of a tube or cylindrical glass-jar containing quicksilver or mercury, and attached to the lower end of a steel-rod in the arc of its oscillation. As the steel-rod lengthens by heat, the mercury expands in volume, and rises in the tube; while, as the rod shortens by cold, it contracts, and sinks or falls. Thus the centre of oscillation remains ever at the same distance from the point of suspension, or upper extremity of the pendulum; or, in other words, the pendulum, in fact, remains ever of the same length.

Graham also conceived the notion of another compound pendulum, composed of different metals, so arranged as to compensate each other by their *difference* of expansion or contraction. This modification of the idea of a compensating pendulum was more fully developed by John Harrison, another celebrated artist, who in 1726 invented the gridiron pendulum, composed of five rods of steel and four of brass, so arranged that the rods which expand the most raise the weight or bob as much as the rods which expand the least depress it. In the annexed fig., the bars marked *s* are of steel, those marked *b* are of brass; the centre rod of steel is fixed at the top to the cross-bar connecting the two middle brass-rods, but slides freely through the two lower bars, and bears the bob B. The remaining rods are fastened to the cross-pieces at both ends, and the uppermost cross-piece is attached to the axis of suspension. It is easy to see that the expansion of the steel-rods tends to lengthen the pendulum, while that of the brass-rods tends to shorten it; consequently, if the two expansions exactly counteract each other, the length of the pendulum will remain unchanged. The relative lengths of the brass and steel bars are determined by the expansions of the two metals, which are found by experiment to be, in general, nearly as 100 to 61. If, then, the lengths of all the five steel-bars added together be 100 inches, the sum of the lengths of the four brass-bars ought to be 61 inches. When the compensation is found, on trial, not to be perfect, an adjustment is made by shifting one or more of the cross-pieces higher on the bars. This pendulum has been greatly improved by Troughton, who substituted for the two pair of brass-rods two cylinders of brass, sliding the one within the other, to which the steel-rods are attached.



Unfortunately, however, this compensation changes, as all metals do, not continuously and gradually, under the influence of heat or cold, but by jerks. The mercurial pendulum, therefore, under certain improvements by Thomas Reid, a talented Edinburgh artist, and by others, has of late been frequently resumed; and it has been found that time-keepers provided with this pendulum and a dead escapement do not vary, on the average, more than a quarter of a second daily—a degree of accuracy wonderful, indeed, when contrasted with the fact that down to the middle of the sixteenth century clocks were incapable of going nearer to accurate time than about 40 minutes within the twenty-four hours, and were nevertheless held to be precision itself compared with all other methods of measuring time then known.*

* Before quitting the subject of pendulums, it is worthy of remark, that their mutual action or sympathy while oscillating near each other on the same wall, so long as they are mutually connected by a rail or shelf common to both, or so long as the cases of the clocks to which they belong are either fixed to each other, or standing on the same flooring plank, is a very singular phenomenon, observed by Hüygens, Ellicot, De Luc, Reid, and many other artists. One pendulum will even stop another, it is said, in such circumstances, and will again cause it to resume its vibrations till it stop, alternately, itself. It has also been found that two clocks with pendulums of nearly equal length and power, or weight, though differing in their measurement of time while apart, will so vibrate in unison when thus connected, as to keep time together with the most surprising accuracy, till they are again separated, or till the plank connecting them be sawn asunder. This singular but not altogether unaccountable influence appears to be not unlike that sympathy of sound between

Other Improvements.

While improvements were effecting in the escapement and pendulum of clocks, the ingenuity of artists was not confined to these alone. Till the beginning of the sixteenth century, clocks were of great bulk, and only fit for turrets or large buildings; and although after this period they were made small enough to be introduced into apartments, there could be no such thing as a really portable clock, far less a watch, till weights and pendulums were got rid of altogether. The substitution of a mainspring for a weight, therefore, constituted a great era in horology, or the science of time-keeping; and this took place about the middle of the sixteenth century, and was shortly afterwards followed by the invention of the *fusee*, a very necessary appendage to the mainspring. But as these inventions completely altered the form and principles of horological machines, and together with that of the spiral escapement-spring, and other improvements, which soon followed that of the pendulum, rather constitute peculiar features of the watch than of the clock—although they were mostly applied at first only to portable time-pieces of the nature of clocks, in which they are indeed still used—we shall reserve the explanation of these ingenious pieces of mechanism till we come to treat of watches. Meantime, there is another part of the works which requires to be here noticed—namely, the

Mechanism for Striking the Hours.

It is not known when the alarm or when the striking-mechanism of the clock was first applied. The alarm was adopted for the use of the Romish priesthood, to arouse them to their morning devotions. The first striking-clock probably announced the hour by a single blow, as they still do, to avoid noise, in most, if not all, of the Scottish churches. In De Wyck's clock, the wheel N, with its projecting pins, served to discharge the striking part, which it has not been thought necessary to illustrate. Like other old clocks, it looked against an interrupted hoop, fixed on what was called the *hoop-wheel;* and the eleven notches on the edge of the plate-wheel determined the hours, or particular number of blows which the hammer should give. During the seventeenth century there existed a great taste for striking-clocks, and hence a great variety of them. Several of Tompion's clocks not only struck the quarters on eight bells, but also the hour after each quarter; at twelve o'clock, 44 blows were struck; and between twelve and one, no less than 118! Many struck the hour twice, like that of St Clement Danes, in the Strand, London, first on a large bell, and then on a small one. Others, again, were invented so as to tell the hours with the least possible noise; also by the aid of two bells, each blow on the small one indicating five hours.

The striking part of a clock is rather a peculiar and intricate piece of mechanism. In ordinary clocks, the impelling power is a weight similar to that which moves the time-measuring mechanism itself; but the pressure of this weight on the striking-machinery is only permitted to come into play at stated periods in course of the workings of the time-keeping apparatus—namely, at the completion of every hour; when the minute-wheel, which revolves once in an hour, and carries the minute-hand of the clock along with it, brings it into action by the temporary release of a catch or detent, permitting the weight wound up on the cylinder of the striking-apparatus to run down for a little, in doing which, the hammer is forced into action, so as to strike the bell. Whether the strokes shall be one or many, is determined principally by two pieces of mechanism, one called a *snail*, from its form or outline, with twelve steps, and the other a *rack*, with twelve teeth; but the intricate action of the whole it would be in vain here to attempt to explain. Suffice it to say, that the time during which the striking-weight is *allowed* to descend, varies according to the turning of the twelve steps of the snail on its axis, and the position of the twelve teeth of the rack, at different hours of the day; being sometimes only long enough to permit one blow to be given by the hammer on the bell, and at another time long enough for twelve such blows.

The lifting piece of the rack-hook, in some clocks, may be raised by pulling a string attached to a small additional piece of mechanism, and thus the clock is made to repeat the hour last struck at any time required—an addition useful through the night, or to the blind. The modes, however, by which clocks as well as watches have been made repeaters, have been very various. Repeating-clocks were first invented by Barlow, an English clergyman, and executed by Tompion in 1676. Some have been made to repeat both hours and quarters at any time, and to indicate the time by blows which might be felt but not heard.

The bells connected with clocks, especially those of churches and other public buildings, are often worthy of notice, either on account of their gigantic size, or on account of the arrangements by which they are made to perform a variety of musical chimes. The largest bell in the world is the 'Monarch' of Moscow, which is above 21 feet in diameter and in height, and weighs 198 tons. It was cast in 1734, but fell down during a fire in 1737—was injured, and remained sunk in the earth till 1837, when it was raised, and now forms the dome of a chapel, made by excavating the space below it. Another bell in Moscow weighs 80 tons. The great bell of Peking, 13 feet in diameter, and 14 feet high, weighs 53½ tons; those of Olmütz, Rouen, and Vienna weigh nearly 18 tons. The most noted bells in Britain are—'Great Peter,' placed in York Minster in 1845, whose weight is nearly 11 tons; 'Great Tom' of Lincoln, 5½ tons; and the great bell of St Paul's, 5 tons. The bell which is to strike the hours in the new Palace of Westminster is to be 8 feet high and 9 feet wide, and will weigh 15 tons; the hammer is to weigh four hundredweights. The metal of which bells are made is generally an alloy of 80 parts copper and 20 tin. An English *bell-metal*, analysed by Dr Thomson, yielded 800 copper, 101 tin, 56 zinc, and 43 lead.

The illumination of clocks was a favourite idea in the seventeenth and eighteenth centuries, and is equally useful in a public way as the striking of hours or the ringing of bells. It was only during the current century, however, that any plan was adopted for public clocks; the first notion being to light them from without, by reflecting the light of a common lamp or gas-jet on their dials. This simple method is still employed, but is vastly inferior to the employment of a translucent dial, with a strongly reflected light from behind. Recently, the pure brilliancy of the Bude-light has greatly contributed to the improvement of this very useful practice.

Curious Clocks.

Various and ingenious, as well as often highly curious, have been the forms and purposes displayed in the construction of clocks, even from their earlier epochs down to the present day. We have already instanced some of an ancient date which pointed out the motions of the sun and moon, the ebb and flow of the tides, &c. Others of a more fanciful description followed. The famous astronomical clock of Strasburg, completed by Isaac

two musical instruments tuned in unison, wherein, when a chord of one is struck, the other, placed in a proper situation, though untouched, responds or echoes back the sounds at first called forth. And as in the combinations of certain medical substances, or in various other combinations, the general result of all the elements is obtained as a steady mean to be depended on, without the special failure, fault, or disadvantage of any one element in the combination, accuracy of time-keeping, of a remarkable kind, might readily be obtained by this singular mode of bringing out, by a combination of pendulum-clocks, an average rate of motion.

Habrecht about the end of the sixteenth century, deserves a prominent place in our catalogue. It has been recently renovated by a M. Schwitgue, after four years' labour; but its original movements are thus described in Morrison's *Itinerary:* 'Before the clock stands a globe on the ground, shewing the motions of the heavens, stars, and planets. The heavens are carried about by the first mover in twenty-four hours. Saturn, by his proper motion, is carried about in thirty years; Jupiter, in twelve; Mars, in two; the Sun, Mercury, and Venus, in one year; and the Moon in one month. In the clock itself there are two tables on the right and left hand, shewing the eclipses of the sun and moon from the year 1573 to the year 1624. The third table, in the middle, is divided into three parts. In the first part, the statues of Apollo and Diana shew the course of the year, and the day thereof, being carried about in one year; the second part shews the year of our Lord, and the equinoctial days, the hours of each day, the minutes of each hour, Easter-day, and all other feasts, and the Dominical letter; and the third part hath the geographical description of all Germany, and particularly of Strasburg, and the names of the inventor and all the workmen. In the middle frame of the clock is an astrolabe, shewing the sign in which each planet is every day; and there are the statues of the seven planets upon a circular plate of iron; so that every day the planet that rules the day comes forth, the rest being hid within the frames, till they come out, of course, at their day—as the sun upon Sunday; and so for all the week. There is also a terrestrial globe, which shews the quarter, the half-hour, and the minutes. There is also the figure of a human skull, and the statues of two boys, whereof one turns the hour-glass, when the clock hath struck, and the other puts forth the rod in his hand at each stroke of the clock. Moreover, there are the statues of Spring, Summer, Autumn, and Winter, and many observations of the moon. In the upper part of the clock are four old men's statues, which strike the quarters of the hour. The statue of Death comes out at each quarter to strike, but is driven back by the statue of Christ, with a spear in his hand, for three quarters; but in the fourth quarter that of Christ goes back, and that of Death strikes the hour with a bone in his hand, and then the chimes sound. On the top of the clock is an image of a cock, which twice in the day crows aloud, and claps his wings. Besides, this clock is decked with many rare pictures; and being on the inside of the church, carries another frame to the outside of the walls, whereon the hours of the sun, the courses of the moon, the length of the day, and such other things, are set out with great art.'

Other ancient clocks displayed processions of saints, with obeisance to the Virgin and Child, &c.; and scarcely a town of any importance was without some curiosity of this sort peculiar to itself. Many curious specimens were invented in the seventeenth century; amongst which were a variety measuring time, or at least moved, by balls running down inclined planes, swallowed up by, and traversing the bodies of, brazen serpents, or descending in metallic grooves, to be again thrown up by Archimedean screws: some were made to go by their own weight, descending inclined planes, and thus avoiding the casualties to which mainsprings and weight-lines are liable; others, by means of springs, were even made to ascend such planes. One clock was simply and ingeniously hung like a lamp from the ceiling, and was kept going by its own descent, the winding up consisting merely of pushing it again towards the ceiling. In another, the dial formed the brim of a plate, filled with water, in which swam a tortoise, turning marvellously with the hour, and ever pointing towards it—by magnetic attraction, as every one would now readily conceive; and this favourite idea was varied by many other simple contrivances. Within the last few years, not a little wonder of a similar kind, we recollect, was excited by a puzzle-clock, with an hour-hand proceeding from the centre of a crystal dial-plate, perfectly transparent, and moving without any visible connection with mechanism. In this case, a piece of glass itself, rotating in the interior of the dial, constituted the requisite mechanism.

More interesting, perhaps, than any of these, and yet of the simplest construction, and of the most common material, are the *electric*, or rather *electro-magnetic clocks*, invented by Mr Bain, formerly of Edinburgh. The prime mover of these machines is the electric currents of the earth, brought to bear upon the machinery, as thus described by a gentleman for whom one of the earliest was constructed. 'On the 28th of August 1844, Mr Bain set up a small clock in my drawing-room, the pendulum of which is in the hall, and both instruments in a voltaic circle as follows:—On the north-east side of my house, two zinc-plates, a foot square, are sunk in a hole, and suspended by a wire, which is passed through the house to the pendulum first, and then to the clock. On the south side of the house, at a distance of about forty yards, a hole was dug four feet deep, and two sacks of common coke buried in it; among the coke another wire was secured, and passed in at the drawing-room window, and joined to the former wire at the clock. The ball of the pendulum weighs nine pounds; but it was moved energetically, and has ever since continued to do so with the self-same energy. The time is to perfection; and the cost of the motive-powers was only 7s. 6d. There are but three little wheels in the clock, and neither weights nor spring; so there is nothing to be wound up.' The electric-clock, as now patented and employed by the Electric-telegraph Company, is somewhat differently constructed. A plate of copper, and another of zinc, buried in the ground to the depth of nine feet, so as to be kept constantly moist, are the generators of the electric current, which is conveyed directly to the pendulum by wires. The pendulum is made of wood, suspended by a steel-spring, and furnished, as usual, with a regulating-bob; the current is conveyed down the wooden rod by wires, to a magnetic coil a little above the bob, and placed in juxtaposition to two permanent magnets, which maintain the oscillation; and about the middle of the pendulum-rod an apparatus is placed on either side, for the purpose of alternately making and breaking the circuit. With the exception of the *break*-apparatus, the whole machine is of extreme simplicity, and little liable to derangement.

Miscellaneous Clock-work.

The applications of clock-work to other purposes than that of measuring time are numerous and important. In all of them, however, the principle is the same—namely, the indication of space, or, what is equivalent, the indication of time or number by mechanical motion. Thus, according to the unit we assume, any amount of space may be indicated either in a regular series, or in a decreasing or increasing series—the increment or decrement taking place progressively, or at intervals, as may be wanted. What can be done with space can be equally accomplished with regard to time or number, and that with an accuracy and precision that no human powers can rival. It was by springs, and weights, and clock-work, that the *automata* which amused our forefathers were moved and directed. Whether they danced or made music, or in whatever way they simulated the conduct of living creatures, it was mechanism that governed their actions—mechanism which would have commanded our admiration the more, that it had been applied to useful purposes. All our *meters*, by which the discharge of gases and liquids are now measured, are but combinations of clock-work; as are also those numerous inventions for *registering* events connected with atmospheric temperature, rise and fall of barometric pressure, direction and force of wind, vigilance of sentinels, and the like.

Thus, by a properly constructed *anemometer* (literally, wind-measurer), not only may the force and direction of the wind be ascertained at any given moment, but the instrument may be made to trace or register the direction from which, and the force with which, the aërial current has swept during every minute of the day—all that is necessary being, to place under the tracing-pencils a clean sheet of paper every twenty-four hours. In like manner, clocks are made for registering the daily fluctuations of the barometer, by means of a pencil floating on the surface of the mercury, and made to traverse a circular card, divided into 365 parts by radii lines, and turned on its centre by the clock once a year. A curious time-keeping method of insuring the presence and attention of night-watchmen has been successfully tried of late years. It consists of a clock with pins projecting round the dial, which can only be pushed inwards at a certain interval, when the watchman's presence and attention are required to unlock the case, and do so, otherwise his neglect, and the exact quarter of an hour at which he was absent, is shewn by the *tell-tale*. Amongst other recent inventions may be noticed a *lock-clock*, to prevent bankers' safes, &c., from being opened except at stated intervals. So also *odometers* (road-meters), or instruments for measuring the space travelled over, whether by pedestrians or wheel-carriages — motion being communicated by the moving body to the clock-work, which is fitted with indices and alarms to indicate any unit of distance required. The same principles have been applied to machines for graduating scales, for engraving tints, and other analogous processes, in which delicacy of line and accuracy of distance are the objects in view.

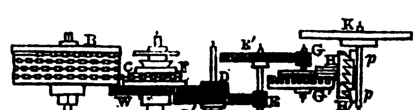
Closely allied to these varieties of clock-work, but evincing a greater degree of scientific skill, are the various machines which have from time to time been invented to lessen the drudgery of long and continuous calculation. The principles upon which the increase and decrease of numbers depend are as fixed as nature herself; and these once known, wheel-machinery of determinate proportions may be constructed to perform every operation in arithmetic with the utmost facility and accuracy. It is well known that in calculations involving the powers and roots of numbers, progression, equations, logarithms, and the like, it not only requires great expertness, but accuracy—an accuracy which is scarcely attainable under the strictest human attention. Such calculations are of indispensable utility in astronomy, navigation, and geography, as well as in general mathematics; and for application, are usually printed in tabular forms, embracing many hundred pages of thick-set figures. To complete such tables with perfect accuracy would require the life-work of several calculators; and yet, by well-arranged machinery, it has been demonstrated that they can be calculated and printed, free from errors, in the course of a few weeks.

The most extensive and ingenious of *calculating-machines* are undoubtedly those invented, and so far perfected, by Mr Babbage. That constructed at the expense of government for the calculation of astronomical and nautical tables, is, we believe, not yet completed, in consequence of some misunderstanding, which caused a suspension of its progress in 1833. This employed 120 figures in its calculation. At a later period, Mr Babbage began another on his own account, intended to compute with 4000 figures! Of the former invention, Sir David Brewster, in 1832, speaks in the following terms:—'Of all the machines which have been constructed in modern times, the calculating-machine is doubtless the most extraordinary. Pieces of mechanism for performing particular arithmetical operations have been long ago constructed; but these bear no comparison, either in ingenuity or in magnitude, to the grand design conceived, and nearly executed, by Mr Babbage.' It appears that the front elevation of the calculating machinery presents seven upright columns, each consisting of eighteen cages of wheel-work, the mechanism of each cage being identically the same, and consisting of two parts, one capable of transmitting addition from the left to the right, and the other capable of transmitting the process of carrying upwards; for it seems that all calculations are by this machinery reduced to the process of addition. There will therefore be 136 repetitions of the same train of wheel-work, each acting upon the other; and the process of addition with which the pen would be going on successively from figure to figure, will here be performed simultaneously, and—as the mechanism cannot err—with unfailing accuracy. The results of the calculating section are transferred by mechanical means to the printing-machinery, and the types are moved by wheel-work, and brought successively into the proper position to leave their impressions on a plate of copper; this copper serving as a mould from which stereotyped plates without limit may be taken.

WATCHES.

Clocks and watches are certainly amongst the most perfect, as, in the civilised world, they are the most indispensable machines ever produced by human ingenuity. 'To become a good watchmaker,' says Berthoud, 'it is necessary to be an arithmetician, in order to find the revolutions of each wheel; a geometrician, to determine the curve of the teeth; a mechanician, to find the forces that must be applied; and an artist, to be able to put into execution the principles and rules which these sciences prescribe. He must know how fluids resist bodies in motion; the effects of heat and cold on different metals; and, in addition to these acquirements, he must be endowed by nature with a happy genius.' No one who has not closely attended to the matter, can conceive the difficulty which has been experienced even in dividing circles for the wheels of a watch into the requisite number of rigorously equal parts, and in 'pitching' them in, or adjusting them one with another. All the resources of art shewn by Ramsden, Troughton, and other eminent mathematical instrument-makers, have been here called into requisition. And as to the delicacy of touch and adjustment necessary in the mere regulation of the mechanism, after being thus accurately made and 'pitched in,' some slight idea may be formed from the fact, which we give in the words of Mr Thomson, that 'a second (a mere pulsation) is divided into four or five parts, marked by the vibrations of a watch-balance, and each of these divisions is frequently required to be lessened an exact 2880th part of its momentary duration!' England has great honour in having advanced the art of watchmaking to its present high condition.

Before entering upon a description of the various parts, we here present the general arrangement of the wheel-work of a common vertical watch—the frame-plates being omitted, and the dial being supposed to be turned downwards. B is the *barrel* or drum, containing the spring which produces the motion. F is the *fusee*, connected with the barrel by the chain *c*. W is the *fusee-wheel*, called also the first or great wheel, which turns with the fusee, and works into the pinion D,



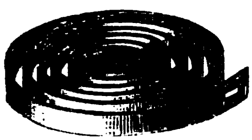
called the *centre-wheel pinion:* this centre pinion, with the centre wheel or second wheel D′, turns once in an hour. The centre wheel D′ works into the *third-wheel pinion* E; and on the same arbor is E′, the *third wheel*, which gives motion to the fourth or *centrate-wheel pinion* G, and along with it the centrate-wheel G′. The

teeth of this wheel are placed at right angles to its plane, and act on the pinion H, called the *balance-wheel pinion;* H′ being the balance-wheel, or *scape*-wheel, or crown-wheel, attached to the same arbor. The balance-wheel acts on the two *pallets p, p*, attached to the *verge* or arbor of the *balance* K; and these being placed at a distance from each other, equal to the diameter of the balance-wheel, and in different places, receive alternately from the scape-wheel an impetus in opposite directions, which keeps up the vibratory motion of the balance. Such is the general arrangement of the powers and motions; we shall now proceed to the analysis.

Mainspring and Fusee.

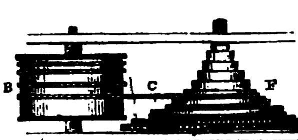
The invention of the mainspring, in place of the weight, was the first pre-requisite to the formation of the watch. But although the mainspring was applied as the maintaining power to time-pieces of a very imperfect description, called watches, about the middle of the sixteenth century, and although the balance had, in such instruments as these, assumed its present form of a vibrating ring, with the greatest weight of course accumulated round a circumference, it was not until the spiral hair-spring was applied to the balance, some time after the invention of the pendulum, as a substitute in clocks for the balance itself, that a comparatively useless machine was converted into a time-measurer nearly as accurate, even in its ordinary form, as the pendulum-clock. Though the invention of the balance-spring, however, was comparatively an early improvement, and the greatest the watch has ever received, we must pass it over in the meantime, till we briefly describe those parts of the mechanism which first rendered the existence of the watch possible at all.

The *mainspring* consists of a coil of thin elastic steel ribbon, enclosed in a miniature barrel or 'drum,' to the inner side of which the outer end of the coil is fixed,



while the inner is fixed to an axis at the centre of the drum, and round which it may be wound or twisted, so as, by its elasticity and recoil, to cause the drum to make as many revolutions as it makes turns itself while it unwinds. Here, then, we have the main power which sets the whole mechanism of the watch in motion. But it is evident that this power, if thus at once applied to the wheels, would cause them to move with less and less rapidity as it became uncoiled, and as its springing power of course became exhausted; so that unless the wheels were so constructed that only the middle turns were required to be in action, and not those in which it is at its greatest or its least power, a force sufficiently equal even for ordinary purposes could not be thus obtained. French spring-clocks, strange to say, are still, in general, made on this defective principle; but English watches and spring-clocks are supplied with a 'fusee,' which corrects the inequalities of the mainspring with a simplicity only equalled by its ingenuity.

The *fusee* is a cone with a spiral groove, attached to the side of the first wheel of the watch, and connected



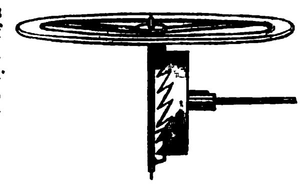
with the barrel or drum containing the mainspring by a chain, hooked, at its ends, to both. The figure to the right, in the above cut, is the fusee; that to the left is the barrel.

In winding a watch, the key is placed on the axis of the fusee, and the chain is wound off the barrel on to the cone of the fusee. When fully so wound, the spring is at its greatest power of recoil; but the chain being then round the smallest part of the cone, the influence of the spring on the wheels is at its least amount; while, just as the power of the spring relaxes and diminishes, the cone enlarges, and its lever-influence hence increases. The fusee, in short, is a variable lever, worked by the mainspring, with more purchase when it has less power, and with less purchase when it has more power. It is a very beautiful contrivance, completely answering the intended purpose, when properly made. By means of a spring contained in the interior of the fusee-wheel, the watch is maintained in motion, while the fusee itself is turned by the watch-key in winding up the mainspring. This is called the *going fusee.* When the watch or spring-clock has no fusee at all —and in very flat watches no fusee *can* be introduced— the barrel is immediately attached to the first wheel. In every case, however, the power of the spring is conveyed through the wheels, by nearly the same arrangement in all watches and clocks, to

The Escapement.

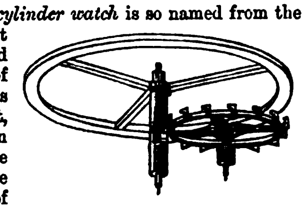
On the peculiar construction of this part of the mechanism, so as best to keep up the vibrations of the balance, the superiority of one watch over another principally depends; though much, of course, also depends on the skill of the workman, and the quality of his materials, in the construction of *every* part of so delicate a machine. The escapement, however, according to its peculiar form, is that by which the watch is chiefly distinguished:—

The *vertical watch* is so named from its old vertical escapement. This



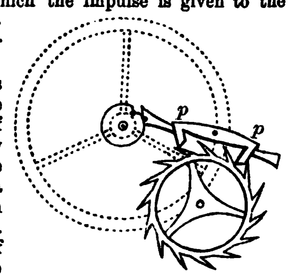
particular mode of escapement is still made in common watches, where it answers sufficiently well; but when applied to clocks regulated by pendulums, is found to be exceedingly defective. The mechanism of this—the *crown-wheel escapement*, as it is technically called—will be readily understood by reference to the preceding figure.

The *horizontal* or *cylinder watch* is so named from the horizontal escapement



of Graham, introduced about the beginning of last century. In this mode of escapement, the impulse is given to a hollow cut in the cylindrical axis of the balance, by teeth of a peculiar form, projecting from a horizontal crown-wheel.

The *lever watch* is so named from the lever escapement of Mudge, in which the impulse is given to the balance by a lever at-



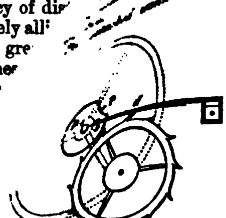
tached to crutch or anchor pallets, *p, p*.

The *duplex watch* is so named from the duplex escapement of Hooke, perfected by Tyrer, in which the impulse is given by a wheel furnished with two sets of teeth. T, T′ are the teeth of repose, lying in the plane of the wheel; *t, t′* are the teeth of impulse, and stand perpendicular to the plane of the wheel; P is

Thus, by a properly constructed *anemometer* (literally, wind-measurer), not only may the force and direction of the wind be ascertained at any given moment, but the instrument may be made to trace or register the direction from which, and the force with which, the aërial current has swept during every minute of the day—all that is necessary being, to place under the tracing-pencils a clean sheet of paper every twenty-four hours. In like manner, clocks are made for registering the daily fluctuations of the barometer, by means of a pencil floating on the surface of the mercury, and made to traverse a circular card, divided into 365 parts by radii lines, and turned on its centre by the clock once a year. A curious time-keeping method of insuring the presence and attention of night-watchmen has been successfully tried of late yea[illegible] It consists of a clock with pins projecting round the [illegible] which can only be pushed inwards at a certain i[illegible] when the watchman's presence and attention ar[illegible] to unlock the case, and do so, otherwise his [illegible] the exact quarter of an hour at which he [illegible] shewn by the *tell-tale*. Amongst other [illegible] may be noticed a *lock-clock*, to prev[illegible] &c., from being opened except at [illegible] also *odometers* (road-meters), or [illegible] ing the space travelled over, [illegible] wheel-carriages — motion b[illegible] moving body to the clo[illegible] indices and alarms t[illegible] required. The same machines for grad[illegible] other analogous [illegible] accuracy of di[illegible]

[illegible] advan- [illegible] successive [illegible] the balance [illegible] and impulse given [illegible] advantage of this [illegible] only one pallet, and [illegible] great accuracy in the [illegible] 'scape-wheel, which is [illegible] the escapements above [illegible] named from the detached escapement of Berthoud, improved by Arnold and Earnshaw, in which the vibrations of the balance are free, or detached from the influence of the crown-wheel, unless at the instant when it receives its impulse and unlocking; the wheels standing still till then.

Closely all[illegible] cing a gre[illegible] machine[illegible] to lesse[illegible] The [illegible] nur[illegible] th[illegible] p[illegible]



In the diagram, P is the main pallet, projecting from the arbor of the balance-wheel, concentric with which is another small pallet *p*, called the *lifting pallet*, which, when the balance is vibrating, lifts a slender spring *s*, so as to set at liberty the tooth held or locked by the detent *d*, which projects from the spring. As in the case of the duplex, the balance here makes two vibrations for each impulse. This mode of escapement, which requires no oil, forms a peculiar feature of the chronometer or marine time-keeper.

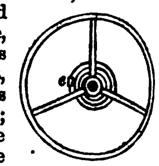
On the respective merits of these different kinds of watches, a few useful hints will be afterwards given. There are many other escapements, but only those now pointed out are in general use.

Balance and Balance-spring.

These are the only other parts of the mechanism of the watch of which it is necessary here to treat.

The balance, as may be seen from the representations of it in connection with the different escapements just noticed, is a wheel finely poised on its axis; the pivot-holes in which it turns being frequently—in chronometers and clocks, as well as in watches—jewelled, or made of small rubies, diamonds, &c., as those of other of the wheels also are, for the sake of durability. The natural effect of an impulse given to such a wheel would be a complete rotation on its axis. This, however, as we have already seen, is convertible, by various escapements, into a vibratory motion. But as in clocks the pendulum was found to be a most invaluable adjunct, absorbing, as it were, in its own more or less extended oscillation, every inequality in the rotation of the wheel-work, or the vibration of the balance, something of work, the mechanism of ea[illegible]. watch-escapements was the same, and consisting [illegible] the balance-spring or hair-transmitting addition fr[illegible], from this analogy, it even other capable of tra[illegible] the pendulum-spring—improperly upwards; for it [illegible] remarks, especially as there is a this machinery [illegible] another description altogether.* There will th[illegible] us as the suggestion of the regulative train of w[illegible] ng, applied to the vibrating mechanism and the p[illegible] ance, in place of either weight or pendu- be goin[illegible] appear, especially after the idea of the be p[illegible] a substitute for the maintaining weight, car[illegible] ggested, this has been held to be a crowning [illegible] in the mechanism of the watch; and the [illegible] its first suggestion has been claimed by no [illegible] three very eminent men—by Dr Hooke; by Hautefeuille, a Frenchman; and by Hüygens, the [illegible] astronomer. It was ultimately proved, that although Hüygens had applied for a patent at Paris in 1674, Hautefeuille had done so several years before; while Hooke had made a similar application in England in 1658. To Hooke, therefore, must be attributed the first idea of the balance-spring.

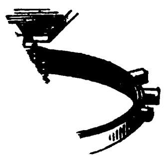
In its application to the balance of a watch, one of the extremities (*e*) of the spring is fastened to a point independent of the balance, while the other is attached near its axis. When the balance is at rest, the spring is inclined neither way, this position being called the point of rest; but when the impulse is given to the balance by the crown-wheel of the escapement, it is clear that now a rotatory motion of the balance cannot take place, even though there should be nothing in the form of the escapement to prevent it; the balance will now only move round so far as the impulse given is able to overcome the elastic resistance of the spring; and when that resistance becomes equal to the impulse given, the balance will stop for a moment, and then be driven back by the elastic recoil of the spring, continuing thus to vibrate so long as the impulse is repeated or the watch is in motion.



The recoil of the spring is sufficient to drive back the balance to a distance nearly double the length of its first motion; this is therefore called the long arc of vibration. But when the motion of the balance is free, with a certain length of spring, the *long* arc of vibration is made in less time than the short one, to which the impulse is given: with a spring of greater length this principle is reversed; whence it was concluded by Le Roy and Berthoud, that equality of time, or *isochronism*, in unequal vibrations, could be more easily obtained by lengthening the spring than by tapering it. In principle, too, the stronger and shorter the spring, the quicker will be its vibrations. Thus effects of an extremely varied description can be produced on the motions of a watch by the slightest difference of length and taper in a hair-spring. And it is thus that the correctness of the time-keeping is essentially dependent on the principle adopted in the formation of this apparently most insignificant little appendage. So much is this the case, that if the hair-spring be isochronal in a free or detached escapement, the time shewn will be the same, notwithstanding changes in the motion of the wheels, or even in the power of the mainspring. In England, where time-keepers have been brought to their greatest perfection,

* This little instrument, the hair-spring, is no less remarkable for the extreme delicacy of its construction, than for the great value which it shews the possibility of giving to a piece of steel, of exceedingly small and insignificant appearance, by manual labour. Four thousand hair-springs scarcely weigh more than a single ounce, but cost often more than £1000! 'The chisel of the sculptor,' as Mr Thomson justly remarks, 'may add immense value to a block of marble, and the cameo may become of great price from the labour bestowed, but art offers *no* example wherein the cost of the material is so greatly enhanced by human skill as in the balance-spring.'

'dered that isochronism is most easily attainable by using the cylindrical helical spring (*s*), which is applied to all marine chronometers.



A recent improvement in watches, or rather in chronometers, invented by Mr Dent of London, consists in coating the ·ing with gold by the electro- ·LECTRICITY), by which means

·tion.

·erfect—in the correction ·spring by a fusee mathe- , in the formation and the ·n of all its wheels and pinions, ·nd execution of its escapement, and ·curacy with which its hair-spring vibrates ·umes—still it will vary in the time it indi- ·s *on every change of temperature*, however slight, unless it be *compensated*.

From what we have already stated in treating of the compensation-pendulum in clocks, the intelligent reader will readily appreciate the difficulties to be here overcome, and will probably conclude, that as in clocks the compensation has been effected by means of the pendulum, so in watches it must have been effected by means of the balance-spring or balance. When completed, the compensation-balance consists of a double or compound rim or ring, the outer part of which is of brass, and the inner of steel, to which the brass is added while in a molten state. The opposite sides of this ring are united by a steel bar, the whole of the steel part, indeed, being filed out of one piece of metal. One half of the ring is then cut or filed away at one side of the bar, and the other half at the other side, as represented in the figure last above given; and the balance is loaded either with small screws, as in that figure, or with sliding weights on each half of the ring, in order to regulate the rate of the chronometer or watch. The compensation, then, is thus effected: an increase of temperature *diminishes* the elastic force of the hair-spring, which would cause the machine to *lose* time; but the same degree of heat expands the outer or brazen part of the ring of the balance more than it does the inner or steel part—brass expanding more than steel by heat, and contracting more by cold—and so, not being able to separate, a curvature of the whole arm of the ring *inwards* ensues, which lessens the inertia or checking weight of the balance; so that the hair-spring now *requires* less force to influence it to the same degree as before; and thus its *loss* of power is *compensated*. On the other hand, cold *increases* the elastic force of the hair-spring, which would cause the machine to *gain* time; but the brass, contracting more than the steel, curves the arm outwards, and increases the inertia, or resistance of the balance, allowing the spring no more influence over it now than it had before.

One defect of this contrivance is, that the balance-spring loses elasticity, by an increase of temperature, at an accumulating rate over the effect produced by the compensation. To remedy this, Mr Loseby has introduced mercury, which, by its fluidity and great thermal expansion, admits of being so adjusted that its effect varies exactly in the same proportion as the change of temperature alters the elasticity of the spring.

The compensation-curb is another instrument for correcting variations in the rate of going from variations in temperature. It limits or extends the length of movement in the hair-spring itself, by a self-moving action, also caused by a difference in the effect of change of temperature on two different metals, and is called a *curb*, from the name of a small piece of mechanism which operates similarly on the balance-spring in regulating a watch by hand.

CHRONOMETERS.

The term *chronometer* is, properly speaking, applicable to all time-keepers, but it is now more usually applied to marine time-keepers only, which are machines of a size between watches and clocks. Some watches, however, made like chronometers in every respect but in size, are called pocket chronometers. But neither of these are anything else than merely such time-keepers as combine all those chief excellences in horological invention just described, including compensation-balance, cylindrical spring, detached escapement, &c., so as to constitute the most accurate time-measurer possible; the purpose of marine chronometers being to discover the longitude at sea; for it is only necessary to ascertain the exact difference in time between two places on different meridians, in order to determine their difference of longitude, or distance eastward or westward of each other. Reverting to what has been already said on this subject, the general reader will at once perceive that so soon as a time-keeper could be made that would keep time with perfect accuracy, such an instrument, set to the time of any seaport, for instance, in Britain—whose precise meridian or longitude was known—and carried abroad in a vessel sailing thence, would afford the means of ascertaining the longitude at sea, by simply observing the instant that the sun reached his meridian there, when, of course, it would be mid-day, or twelve o'clock noon; and at the same time observing the difference between this time and that shewn by the time-keeper, which would necessarily be different if the longitude was different—the amount of the difference giving him his longitude, on the calculation that 15 degrees east or west make *one hour* of time, or 15 geographical miles *one minute*. If, for example, the time-keeper had been set to time at the meridian of Greenwich Observatory [where, in fact, chronometers are now usually adjusted, and where a signal hoisted every day on the instant that twelve o'clock strikes, or rather on the instant that the sun arrives at the meridian there, proclaims the true time of day, on that meridian, to all the mariners in sight of it, that they may be able, without trouble or mistake, to adjust their chronometers accordingly], and if it was but eleven o'clock on the time-keeper thus set, when it was twelve o'clock or mid-day at the time and place where the meridian was taken at sea, then that place must have been in longitude 15 degrees *east* of the meridian of Greenwich; if, on the other hand, it was one o'clock instead of eleven at that moment, the longitude must have been 15 degrees *west*, not east, of the meridian of Greenwich. By knowing also the time when any particular star passed the meridian at Greenwich, the navigator, in a similar manner, could calculate his longitude by an observation of the same star at sea. Lunar observations, eclipses, or the like, might be made use of on similar principles.

It was a clear perception of the fact, that the longitude might thus be at any time determined, could time-keepers be made to measure time with accuracy, that led Sir Isaac Newton and others to recommend to government the offer of a public reward for the accomplishment of so desirable an object; and it was the hope of reaping the splendid reward of £20,000, which government accordingly did offer, that formed the very mainspring to all those high exertions of horological ingenuity which led to the final success of John Harrison, after an unwearied labour of forty years—a success which, in turn, resulted in the present highly advanced state of horology.

USEFUL HINTS.

For the attainment of habits of punctuality, for the regulation of the usual routine of business and of

everyday life, for the morning's timely arousement and the evening's sufficient repose, and for other and innumerable purposes of convenience, necessity, and pleasure, much, in reality, often depends on the judicious selection of a time-keeper. And even the character of a young man has been known to be much influenced by the quality of his watch, the possessor of an accurate time-keeper becoming ambitious to emulate its excellence, and thus gradually acquiring habits remarkable for punctuality. It is therefore to be regretted—even though in many cases a very indifferent time-keeper may be thought all that is required for general purposes—that no efficient instruction can be given to the inexperienced, especially towards the selection of a watch, as none but a workman possessing the highest knowledge of his art is capable of forming a correct opinion of its relative merits. The hints given by a skilful and practical artist himself, however, who has had years of the most attentive and constant experience, cannot but be deemed invaluable; and as such we would especially recommend to the inexperienced in horology, a popular little volume, published by Messrs Boone of New Bond Street—namely, Thomson's *Time and Time-keepers* for the useful as well as pleasing and interesting instruction with which it is stored.

Amongst many valuable hints for the proper selection of time-keepers contained in Mr Thomson's little volume, we shall take the liberty of briefly instancing the following; and first of clocks:—These, in general, measure time more accurately than watches, especially eight-day weight or long-clocks, which are also cheapest. Long and heavy pendulums are to be preferred. A light pendulum shews a clock to be badly constructed, or deficient in power. Steel rods are better than brass, well-seasoned and varnished wood than steel, and compensation-rods than either. The clock should be steadily fixed to the wall, or firmly placed on *three* feet sufficiently far apart, so that the mechanism may be uninfluenced by the oscillations of the pendulum. Clocks are regulated by lengthening the pendulum, to make them lose, and by shortening it, to make them gain; this is very generally done by turning a nut or screw *below* the weight or *bob* of the pendulum, *to the right to gain*, or *to the left to lose;* or, if the screw is *above* the weight, the rule is *reversed*. Many French clocks, and a few old English ones, are liable to derangement in striking, unless the hands are moved rapidly *forward*. The hands of English clocks, in general, may be turned either way without injury, and the same with a watch, unless it has an alarm.

An intelligent, careful man may be safely trusted with the cleaning, adjusting, or repairing of clocks, while a diversity of talent and experience is necessary to qualify him for the manipulation of watches. 'The possessor of a good picture would doubtless inquire into the ability of the artist before he intrusted him to retouch it; and this caution is equally necessary for a watch, as many of the best construction have sustained irreparable injury from the hands of unskilful workmen. Even bad watches—which are by far the greatest number—require the aid of better hands than those which constructed them.' A clever artist may enable even a bad watch to perform tolerably well. Watches should ordinarily be cleaned every second or third year; small, flat, or complicated ones oftener. All require care in handling. They should be regularly wound as nearly at the same hour as possible; and while being wound, should be held steadily in the hand, so as to have no circular motion themselves. When hung up, let the watch have support, and be perfectly at rest; or when laid horizontally, let it be placed on a soft substance for more general support, otherwise the motion of the balance will generate a pendulous motion of the watch, causing much variation in time. Should a watch vary by heat or cold, as when worn or not worn in the pocket, the hands may be set to time; but the regulator should not be altered, if set to the ordinary temperature of the season. Compensation watches, if properly constructed, do not so vary. A trial even of a year or two is no proof of the substantial worth of a watch. Dealers themselves may be deceived. A duplex watch may be very bad, while a vertical one may be very good, so that workmanship is as important as principle. Many low-priced and bad watches have eight or even ten holes jewelled, while many good and costly ones have but four: a hole can be jewelled for three shillings. 'The high-sounding description, the handsome exterior, the offered trial, and enticing cheapness, are effective baits to the short-sighted.' External ornament forms but a small item of expense, and the prices therefore will, in general, point out the comparative qualities of the work in the shop of an artist of known integrity and ability.

The large thick old watch is less absurd than some recently made, little thicker than half-a-crown, or even much smaller, as in the latest and rarest novelty amongst the beautiful and ingenious Genevese watches, some of which little exceed the size of a shilling. The lever watch is capable of great accuracy, and is preferable to the vertical, though the principle of the latter is more generally understood, and more easily repaired; lever watches, however, are neither expensive to repair nor liable to derangement. The horizontal or cylinder watch is liable to great tear and wear, but performs with considerable accuracy. The duplex watch, with a compensation-balance, when well constructed, and treated with ordinary care, will keep time with the greatest accuracy; but being delicate, it does not stand violent exercise: a bad duplex watch is most expensive to repair. The detached watch, the escapement of which is the only one used in marine chronometers, is the most perfect, but requires care. Repeaters are expensive to repair as well as to purchase, but may be as accurate as others. Watches shewing seconds are often useful, and, if well made, are neither expensive nor easily deranged. A watch may be handsome, yet bad; but a good watch is seldom unsightly. The spring for shutting the shells is not so good as the snap; it often allows dust to penetrate to the works. The covers of hunting-watches will not protect the glass when the hunters are very flat. The extreme accuracy of marine chronometers is partly produced by their being kept constantly in a horizontal position. They are only required to shew *equal* time; whether they gain or lose is of little consequence, provided they are regular, and *keep* their known rate.

CHEMISTRY.

THE material world immediately under our observation, including such parts of the earth's crust as have been explored, the plants and animals upon its surface, and the atmosphere which envelops it, is found to consist of sixty-two simple substances, just as all the words which compose a language are resolvable into a few letters. These substances, having hitherto resisted all endeavours to divide or resolve them into any others, are termed the *elements of matter*, or *simple bodies*. By this it is not peremptorily affirmed that there are only sixty-two elementary substances in nature; neither is it maintained that these substances are absolutely simple, and incapable of being reduced to fewer elements, or even, as some chemists have hinted, to a single primary element, of which all other bodies are but conditional phases. All that is here meant is, that at present there are upwards of sixty substances which cannot be reduced, by the known processes of chemistry, to any other condition. The investigation of the laws under which these various elementary bodies have formed the numerous compound substances which we see in nature, and the means by which compound substances can be resolved into their original elements, or simple elements thrown into new combinations, are the objects of the science of Chemistry.

The term *chemistry* is of doubtful derivation; but it seems to have been applied at an early period to various methods of melting or preparing metals, and was identified with the visionary efforts of alchemy, which professed to be the art of transmuting copper and other base metals into gold and silver. It is only within the last seventy or eighty years that chemistry has risen to the rank of a science; but during that period, it has advanced towards perfection with a rapidity unparalleled in the history of philosophy. The applications of chemistry are universal. There is no science so immediately conducive to human comfort. To whatever art or manufacture we turn our attention, we find that it has either been created by chemistry, or owes to it some of its greatest improvements. In the present sheet, it is our object to present a simple and intelligible view of the *principles* of this exceedingly important science, reserving its *applications* in the industrial arts for subsequent treatment.

CHEMICAL ATTRACTION.

When particles of different kinds of matter are brought into contact, they frequently unite, and form new substances, differing widely in many instances from those by whose union they have been formed. This is called *chemical attraction* or *chemical affinity;* because it is said that the particles of certain bodies, having an affinity for each other, will unite, while others, having no affinity, do not enter into union. It might almost be supposed that there are such things as preferences and dislikes among the particles of matter. Thus, if a piece of marble be thrown into vitriol or sulphuric acid, their particles will unite with great rapidity and commotion, and there will result a compound, differing in all respects from the acid or the marble. This is at once an instance of affinity between two substances, and an exhibition of stronger and weaker affinity. The commotion or effervescence in the experiment arises from the disengagement of a gaseous (carbonic) acid in combination with the basis of the marble, in consequence of the sulphuric acid having a stronger affinity for it. When a piece of caustic magnesia is thrown into vitriol, we have a case of simple affinity, with a complete change also of properties. All their elements combine, without any disengagement, and the result is the production of Epsom salts, a compound with properties entirely new. Neither ingredient has been destroyed; they can again be extracted pure from the compound; but they have changed their characters through the force of affinity. But if a piece of quartz or gold be thrown into the acid, no change is produced in either, because the particles of the respective substances have no affinity for each other.

This process of affinity is termed in chemical language *combination*, and is quite distinct from *aggregation*, which is the union of particles of a similar kind, forming a mass which has the general properties of the particles of which it is composed, whatever may be its structure or form. It is also to be distinguished from *mechanical mixture*, in which the particles, although they may be intimately blended, are not amalgamated with each other, so as to lose their own individual properties. The difference between chemical combination and mechanical mixture will be clearly seen from the following example:—If into a crystal bottle we pour a portion of oil and a quantity of water, and shake them well, the two substances can never be made to unite permanently together. Although they appear to do so for a short while after the experiment is made, yet if the vessel be allowed to stand for a sufficient length of time, the particles of water, being heavier than those of oil, will descend to the bottom, while those of the oil will rise upon the top. Here it is evident that no chemical attraction has been exerted between the particles of the two bodies, because no chemical change has taken place. In a word, there has been a mechanical mixture, without any chemical combination. But if with the water in this experiment we add some potash, the results will be very different: the particles of the bodies will intimately combine with each other, and a compound will be formed having properties entirely different from either the oil or the potash. The compound substance thus obtained is the useful article soap.

It sometimes happens that two bodies will readily combine with each other, but if a third body be added, the combination will be destroyed; the first of the two bodies having a stronger affinity for the third than it had for the second. Thus, if magnesia be dissolved in nitric acid, a complete union takes place; but if lime be added to the compound, the nitric acid unites with the lime in preference, and the magnesia, which was formerly dissolved, falls, or is *precipitated*, to the bottom of the vessel. Again, if a piece of aqueous sulphate of copper (common blue vitriol) be suspended by a thread in a glassful of water, the crystals shortly disappear, and the whole fluid becomes tinged with blue. Here the solid is said to be *dissolved*—that is, the cohesion of its particles is destroyed, and the compound is called a *solution* of the solid. Such a solution differs entirely from chemical union, and is merely a very perfect mechanical mixture—the same as if we had dissolved sugar in water, or salt in water. The restoration of cohesion to a body after it has been deprived of it, is exhibited in a great variety of instances. For example, if a quantity of sugar be dissolved in water, and the solution be allowed to stand till the water has evaporated, the attraction of cohesion will take effect between the particles of the sugar, which will again resume the solid form. Here, however, a remarkable circumstance has occurred: whatever the state of the sugar may have been originally, it invariably, in resuming its solidity, assumes a particular form, one of great regularity and beauty. It was formerly opaque, it is now transparent; originally a shapeless mass, it

is now a prism of six sides, surpassing in lustre and symmetry the products of the lapidary's wheel. This solid spontaneous production is called a *crystal;* the process by which it is produced, *crystallisation;* and the science, the object of which is to study the forms of crystals, *crystallography.*

Bodies, whether solid, liquid, or gaseous, are susceptible of assuming the *crystalline* form, and the substances which do so are numberless. The shapes which the crystals take, and the facility with which they assume them, are various. Instances of crystallisation, such as sea-salt, Epsom salts, saltpetre, are familiar to every one. Water, it is well known, when cooled to a certain degree, assumes the form of ice, which is crystalline. There are three methods of producing artificial crystals: first, by dissolving the substance in a hot liquid, and either allowing the solution to cool, or evaporating it by continued heat; second, by making the substance assume the aërial form; and third, by melting it by fire without the presence of a liquid, and allowing it to cool slowly. The first two are the most common methods of forming crystals; and by the third, sulphur, spermaceti, bismuth, &c., may be made to assume the crystalline state. If as much alum be put into boiling water as the water will readily dissolve, crystals will be deposited as soon as the liquid cools. The presence of the atmosphere has considerable influence upon the formation of crystals. If as great a quantity of Glauber salt (sulphate of soda) be dissolved in a flask half filled with boiling water as the water will hold in solution, and the flask be corked, no crystals will be formed as the liquid cools. Remove the cork, however, and crystallisation commences as the air enters, a solid crystalline mass being almost instantaneously formed. If the weather is warm, crystallisation will not perhaps take place even after the solution is cool. In this case, the introduction of a small crystal into the flask will instantly induce the process of crystallisation.

The same body does not invariably exhibit the same form of crystals; there may be several forms of crystals belonging to one body, but in one or other of these it is sure to crystallise, and not according to any other form. It is also to be observed that very different kinds of matter may crystallise after the same model.

The general name for the substance formed by chemical attraction is a *chemical compound;* the substances of which it is composed are called its component or *constituent parts,* or *ultimate elements.* The separation of these is termed *decomposition;* and when decomposition is performed for the purpose of ascertaining the ultimate composition of a body, it is named *chemical analysis.* The reunion of the constituent parts is denominated *chemical synthesis.* Integrant particles of a body differ from the constituent particles thus:—The latter are the most minute parts into which a compound body can be resolved by decomposition, and are hence of a different nature, both with regard to each other, and the substance itself which their mutual union gives rise to. The integrant particles are the most minute parts into which any body can be resolved *without* decomposition.

LAWS OF COMBINATION AND DECOMPOSITION.

There are various laws connected with, and phenomena attendant upon, chemical attraction. While this force can operate only between bodies of a different nature, the qualities which characterise these bodies when separate are changed or annihilated by their combination. Thus, not only their active properties, but their density, temperature, form, colour, taste, smell, and sonorousness are generally affected. Chemical attraction can take place between two, three, or even a greater number of bodies. The force of chemical affinity between the constituents of a body is estimated by that which is requisite for their separation. It has been already remarked that the degree of attraction varies very considerably in different bodies; and it is evident that from this variation all chemical compositions and decompositions take place. The preference of uniting with another substance which any given body is found to exercise, is metaphorically termed *elective attraction* or *affinity.* It is of two kinds, each of which derives its appellation from the number and the powers of the principles which may be brought into contact with each other. When a simple substance is presented to a compound one, and unites with one of the constituents of the latter, so as to separate it from that with which it is combined, and by this means produce a decomposition, it is said to be effected by *single elective affinity.* Some substances, however, will not be thus easily decomposed; and it is found necessary to introduce two or more principles, in order to effect the end in view. When two principles, therefore, are presented to a compound body, and when the principles unite each with one of those of the compound substance, two new substances are formed; and all instances of decomposition in this manner are said to be effected by *double elective affinity.* It is to be observed that all changes effected in this manner are permanent, and that the new compound thus formed cannot be decomposed, until a substance having a more powerful attraction for one of its constituents than they have for each other, is brought into contact with them.

To Sir Isaac Newton we are indebted for the first attempt at a rational explanation of chemical combination. He was of opinion that the minute atoms of certain bodies attract each other with an unknown but enormous force, which begins to exert itself only when the particles are at very small distances from each other, and that, accordingly, this force exerts itself, and the bodies unite when they are brought within the requisite distance. These views slowly made their way into the science; but towards the middle of the eighteenth century, they seem to have been almost universally adopted. The term chemical affinity was substituted for that of attraction, and the strength of the affinity existing in bodies came to be measured according to the order in which they were decomposed. It is unnecessary to mention the various tables of affinity which were published previously to that of Bergman, who, in 1775, gave to the world a copious table of affinities, and appears to have fixed the opinions of chemists in general to his own views of the subject. According to this philosopher, the affinity of each of the bodies, say a, b, c, d, for x, differs in intensity in such a manner, that the degree of affinity in each may be expressed by numbers. He supposed affinity to be elective, in consequence of which, if a have a greater affinity for x than b, if a be presented to the compound bx, a decomposition will ensue, b will be set at liberty, and a new compound ax will be formed.

ATOMIC THEORY.

This theory was not discovered all at once, and immediately acknowledged by chemists; it was gradually brought to light by the repeated experiments of successive philosophers, of whose labours, however, it will be impossible to exhibit a view in this place. To our countryman Dalton, we are indebted for the first development and demonstration of the fact, that bodies unite in definite proportions; and of this law we shall now present as clear and simple a view as possible. Whilst engaged in determining the composition of the two gases called severally carburetted hydrogen and olefiant gas, he discovered that for complete combustion they require *different* but *determinate* quantities of oxygen gas. One volume—that is, any stated measure—of carburetted hydrogen requires two volumes of oxygen gas, whilst a volume of olefiant gas requires three.

The conclusions at which Dalton arrived were, that bodies consist of *atoms,* incapable of further diminution or division; that in chemical combinations it is these ultimate particles which unite; and that in the case above mentioned of the combustion of the two inflammable gases, carburetted hydrogen is a compound of two atoms of hydrogen and one atom of carbon; whilst

olefiant gas is a compound of two atoms of hydrogen and *two* atoms of carbon. The atoms he considered as spheres, and represented them by such symbols as a circle with a dot in the centre, a circle with a vertical diameter, and the like. In this manner the composition of a number of the best known bodies was represented by him, and the ratios of the weights of the atoms of the simple bodies inferred. For instance, he concluded from his experiments that carburetted hydrogen is composed of—hydrogen two, and carbon six; while olefiant gas is composed of—hydrogen two, and carbon twelve. Now, as the latter gas consists of two atoms of hydrogen and two atoms of carbon, then the weights of these atoms are to each other in the relation of one to six. If the weight of the atom of hydrogen, therefore, be represented by one, that of carbon will be six. In this manner, the ratios of the weight of the atoms of all the simple bodies may be ascertained by a careful analysis of the compounds formed by their union.

The combinations of mercury or quicksilver with some other bodies afford an illustration of the theory. Its first compound with oxygen, one of the gases of which the atmosphere is composed, consists of 200 parts of mercury, and eight of oxygen. If, however, the metal be subjected to a considerable degree of heat, it will be converted into a red shining mass, which is also a compound of the metal with oxygen; but in the latter case, eight parts of oxygen have united with 100 parts of the metal. The explanation of this is, that eight is the chemical equivalent of oxygen, and 100 that of mercury. In every successive compound which they make, their proportions form a multiple of one or both equivalents. Every other simple body has, in like manner, its equivalent number, and to its compounds the same rule applies. Innumerable instances of this might be adduced, but these are sufficient to prove the remarkable truth, that when different substances combine by chemical attraction, the proportions of the ingredients are always uniform; that for every atom present of one substance, there is exactly one, or two, or three, &c., of the other. If, for instance, any quantity of sulphur, intermediate between the two combinations of that substance with mercury, be added, it will not combine with it, but remain as a foreign ingredient in the sulphuret of mercury, as the compound is termed. All bodies, however, do not unite in several proportions, thus giving rise to several distinct compounds from two elements; there are many elementary bodies which will only unite with each other in one proportion, so that any two of such substances can only form one compound. This law, however, is not universal, as it is well known that water and alcohol, and water and sulphuric acid, will unite in any proportions. Water will also unite in any proportion with soluble salt, until it becomes completely saturated. Bodies which unite in any proportions form an infinite variety of compounds, and are distinguished by their being united by a weak affinity (not worthy of the name of *chemical affinity*), and also by the compounds formed, differing little from their simple constituents or from each other.

EQUIVALENT RATIOS—SYMBOLS—CLASSES.

The result of investigations of chemical unions has been the formation of scales exhibiting the equivalent ratios of the simple elements, expressed in numbers. For this purpose, it is evident that some body must be fixed upon, and expressed by unity. Hydrogen gas, being the lightest known body in nature, and combining in the smallest proportion by weight with the other simple substances, has been taken as a standard of comparison for the combining proportions or *equivalent numbers* of all other bodies. Oxygen has also, by the continental chemists, been taken as the standard of comparison, and represented by 100. Water is a compound of eight parts by weight of oxygen, with one part by weight of hydrogen; which two gaseous bodies we shall afterwards describe. Whenever hydrogen and oxygen gases are burnt in the proportion stated, they invariably form water; and they cannot be made to combine completely in any other proportion. From this, Dalton concluded that water is a compound of one atom of hydrogen and one atom of oxygen. But the weight of the latter gas being eight times that of the former, then it followed that the atom of oxygen was just eight times heavier than the atom of hydrogen. Hence if the latter be represented by one, then will the former be represented by eight, according to those who take hydrogen as the standard. Those who take oxygen as the standard, and represent it by 100, make the equivalent for hydrogen 12·5; the result is of course the same, the proportion of 12·5 to 100 being exactly the same as that of 1 to 8. These observations lead us to speak of the doctrine of volumes, so generally embraced by chemists. The union of gases is always effected in simple proportions of their volumes; and a volume of one gas combines with an equal volume, or twice or three times the volume of another gas; and in no intermediate proportion.

The impracticability, in many cases, of contriving convenient names expressive of the constitution of chemical compounds, especially of minerals, suggested the employment of *symbols* as an abbreviated mode of denoting the composition of bodies. It was thought that the names of elementary substances, instead of being written at full length, might often be more conveniently indicated by the first letter of their names; and that the combination of elements with each other might be expressed by placing together, in some way to be agreed on, the letters which represent them. The advantage of such a symbolic language was felt so strongly by Berzelius, that he contrived a set of symbols, which he has since used extensively in his writings; and other eminent chemists, as well as mineralogists, believing symbols to be useful, adopted those which Berzelius used. The consequence is, that symbolic expressions, called *chemical formulæ*, are now almost universally employed in the language of chemistry. The following table exhibits the names of

THE ELEMENTS, WITH THEIR SYMBOLS AND EQUIVALENTS.

Elements.	Symb.	Equiv.	Elements.	Symb.	Equiv.
Aluminum, .	Al	13·7	Nickel, . .	Ni	29·6
Antimony (*Stibium*), . .	Sb	129·	Niobium, . .	Nb	
Arsenic, . .	As	75·	Nitrogen, .	N	14·
Barium, . .	Ba	68·5	Norium, . .	No	
Beryllium, . .	Be	6·9	Osmium, .	Os	99·6
Bismuth, .	Bi	213·	Oxygen, . .	O	8·
Boron, . .	Bo	10·9	Palladium, .	Pd	53·3
Bromine, .	Br	80·	Pelopium, . .	Pe	
Cadmium, . .	Cd	56·	Phosphorus, .	P	31·
Calcium, . .	Ca	20·	Platinum, . .	Pt	98·7
Carbon, . .	C	6·	Potassium (*Kalium*), . .	K	39·
Cerium, . .	Ce	47·?	Rhodium, . .	R	52·2
Chlorine, . .	Cl	35·5	Ruthenium, .	Ru	52·2
Chromium, .	Cr	26·7	Selenium, . .	Se	39·5
Cobalt, . .	Co	29·5	Silicium, . .	Si	21·3
Copper (*Cuprum*),	Cu	31·7	Silver (*Argentum*),	Ag	108·
Didymium, .	Di	50·?	Sodium (*Natrium*),	Na	23·
Erbium, . .	E		Strontium, . .	Sr	43·8
Fluorine, .	F	19·	Sulphur, . .	S	16·
Gold (*Aurum*), .	Au	197·	Tantalum, . .	Ta	184·
Hydrogen, .	H	1·	Tellurium, .	Te	64·
Iodine, . .	I	127·	Terbium, . .	Tb	
Iridium, . .	Ir	99·	Thorium, .	Th	59·6
Iron (*Ferrum*), .	Fe	28·	Tin (*Stannum*), .	Sn	58·
Lantanium, .	La	47·?	Titanium, .	Ti	25·
Lead (*Plumbum*),	Pb	103·7	Tungsten or Wolfram, . .	W	92·
Lithium, . .	Li	6·5	Uranium, .	U	60·
Magnesium, .	Mg	12·	Vanadium, . .	V	68·6
Manganese, .	Mn	27·6	Yttrium, .	Y	
Mercury (*Hydrargyrum*), .	Hg	100·	Zinc, . . .	Zn	32·6
Molybdenum, .	Mo	46·	Zirconium, .	Zr	33·6

Applying these symbols, HO represents water—that is, one equivalent of hydrogen and one of oxygen; SO_3, sulphuric acid—that is, one equivalent of sulphur and three of oxygen; and in the same manner, NO_5, nitric acid; HCl, hydrochloric acid; and so on. The

brevity and lucidity of the system are admirable; and to the chemist, a few lines of properly constructed formulæ convey more information than pages of description, and with less risk of misconception and error.

For the convenience of study, the sixty-two elementary substances have been arranged into classes. One system of classification, and that which we adopt, is dependent upon the elements being metallic or non-metallic. 1*st*, The NON-METALLIC elements are thirteen in number—namely, oxygen, hydrogen, nitrogen, carbon, boron, silicon, sulphur, chlorine, bromine, iodine, fluorine, selenium, and phosphorus. Oxygen, chlorine, bromine, iodine, and fluorine, having a tendency to combine with almost all other substances, and their union being generally accompanied by light and heat, have been termed *supporters of combustion;* and the four latter, from their similarity in habitude and properties, have received a common termination—namely, *ine.* For the same reason, carbon, boron, and silicon have *on* annexed. 2*d*, The METALLIC elements are forty-nine in number, of which the more important are—potassium, sodium, barium, strontium, calcium, magnesium, aluminum, chromium, zinc, manganese, nickel, cobalt, iron, lead, silver, mercury, copper, bismuth, cadmium, gold, platinum, antimony, tin, and arsenic. The more rare, and, commercially speaking, less important metals, are—beryllium, cerium, didymium, erbium, iridium, lantanium, lithium, molybdenum, niobium, norium, osmium, palladium, pelopium, rhodium, ruthenium, selenium, tantalum, tellurium, terbium, thorium, titanium, tungsten, uranium, vanadium, yttrium, and zirconium.

ACIDS, SALTS, METALLIC OXIDES, EARTHS, ALKALIES.

Acids are a most important class of chemical compounds, and have the following characteristic properties:—The greater number of them have a sour taste, and are very corrosive. With few exceptions, they change vegetable blues to red, they are mostly soluble in water, and they unite with the alkalies, earths, and metallic oxides, forming what are called *salts*—an order of bodies of the highest importance in the arts, manufactures, &c. Some acids are destitute of a sour taste, but their affinity for the three classes of bodies above named is a universal characteristic. Acids are all compound bodies, and some of them have more than one *basis* or radical. There are a number of acidifying principles, but oxygen is the most extensive one. The acid is distinguished by the name of its characteristic ingredient, and its degree of oxidation—that is, the quantity of oxygen it contains, is marked by the termination in *ous* or *ic*, or by the prefix *hypo* (under). The highest degree of oxygenation is marked by the termination *ic*, as nitric acid, and the salt which is formed from it is made to terminate in *ate*, as nitrate of potash; the next by that of *ous*, as nitrous acid, and the salt which is formed from it is made to terminate in *ite;* and the lowest by *hypo*, as the hyponitrous acid. Sometimes oxygen combines in a greater quantity with the acidifiable radicals, in which case the product is said to be superoxygenated. All acids are not susceptible of these various degrees of oxygenation, some being limited to only one. There are a considerable number of acids; but of the more important there are few, and these we shall notice as we come to treat of the several elements.

A *salt* is the term usually employed to denote a compound, in definite proportions, of acid matter with an alkali, earth, or metallic oxide. When the proportions of the constituents are so adjusted that the resulting substance does not affect the colour of infusion of litmus or red cabbage, it is then called a *neutral* salt, because the peculiar powers of both bodies are suspended and concealed; they are rendered neutral or inactive. When bodies combine in such a way as to satisfy their mutual affinities, they are said to *saturate* each other. When the predominance of acid is evinced by the red of these infusions, the salt is said to be acidulous, and the prefix *super* or *bi* is used to indicate this excess of acid. If, on the contrary, the acid matter is deficient, or short of the quantity necessary for neutralising the alkalinity of the base, the salt is then said to be with excess of base, and the prefix *sub* is attached to its name. These must be understood, however, only as general rules. There are exceptions to be found in the case of some salts, as the compounds formed by an acid and an alkali, an earth, or a metallic oxide, are denominated. For example, a certain salt formed by nitric acid and lead, though the acid be perfectly neutralised, reddens vegetable blues; and a salt formed by boracic acid with soda retains the powers of an alkali, in the respect in question, though with a double proportion of acid in it. A *double salt* is a compound of two salts—as, for example, tartrate of potassa combined with tartrate of soda, or sulphate of potash and sulphate of alumina in ordinary alum.

Metals, such as iron, copper, lead, &c., are familiarly known to every one, but there are a great many others which are very rarely to be met with. The following are some of the characters which distinguish metals from other bodies:—They are for the most part hard and heavy, and are all opaque; insoluble in water; they possess a peculiar lustre; admit of being so highly polished as to reflect light; are capable of being melted by heat, and of recovering their solidity by cooling; most of them may be extended by hammering, and all are rapid conductors of electricity. They are of various colours, and require different degrees of heat to fuse or melt them. They generally occur in the earth in what are called *veins* (excepting iron, which is found in *strata*), and are seldom found in the pure metallic state, but generally in combination with some other substance, in which state they are called *ores*. The metals, which are all simple bodies, will be individually noticed afterwards. (See also METALS AND METALLURGY.) Most of them, when subjected to heat until they become melted, combine with the oxygen of the atmosphere, and form what are called *oxides*. Oxides are destitute of those properties which distinguish the metal from which they are formed. Instead of being bright, shining, elastic, and ductile substances, they are generally a dry, earthy-looking powder. Other substances, besides metals, however, are capable of being converted into oxides; and it must be kept distinctly in view, that in every case there is not so much oxygen imparted as will produce *acidification*. Oxygen frequently combines in various proportions with a substance, rendering it an oxide, but without advancing it to the state of an acid. In order to distinguish each compound thus formed, the language of chemistry is very systematic. The first is called a *proto*xide; the second, a *deut*oxide or *bin*oxide; the third, a *trit*oxide or *ter*oxide; and the highest degree of oxidation, a *per*oxide. The Latin term *sesqui* (one and a half) denotes that the elements exist in a compound, in the ratio of one and a half—as the sesqui-carbonate of ammonia. When a simple non-metallic substance combines with another, with a metal, or with a metallic oxide, the name of the compound terminates in *uret*—as carburet of iron, sulphuret of mercury, &c.

The term *earths* was formerly, and is still, but in a modified sense, applied to several substances which compose all the various rocky substances, clays, and soils which constitute the crust of the globe. They are tasteless, inodorous, dry, uninflammable, sparingly soluble, difficult of fusion, and of moderate specific gravity. These bodies will be more particularly described when we come to treat of their metallic bases.

Alkalies may be defined as bodies which combine with acids so as to impair or neutralise their activity, and produce what are called salts. They are distinguished by properties the reverse of acids, and the two classes are generally looked upon as antagonist substances. Besides the power of neutralising acids, there are four alkalies—namely, potash, soda, ammonia, and lithia—which possess the following properties in a high degree:

They change vegetable blue to green, red to purple, and yellow to a reddish brown; they have an acrid and urinous taste; they are powerful corrosives of animal matter, with which they combine so as to produce neutrality; they also unite with oils and fats, forming the well-known substance soap; they combine with water and alcohol in any proportion. Four of the earths —namely, lime, baryta, strontia, and magnesia—possess alkaline properties to a considerable extent, and are hence called *alkaline earths*. These bodies differ from the pure alkalies, inasmuch as they become insoluble in water when neutralised by carbonic acid. Moreover, alkalies possess the power of changing vegetable colours *after* being saturated with carbonic acid, and by this criterion they are distinguished from alkaline earths.

It was long observed that the properties of earths very nearly resemble those of the compounds of oxygen and metals called metallic oxides; but it remained for the brilliant genius of Sir Humphry Davy to shew that both the earths and alkalies are metallic oxides. It thus appears, then, that the globe is one vast mass of various kinds of metals, disguised by various substances, but chiefly by oxygen. Earths and alkalies are simply metallic oxides; whilst a further impregnation of these substances with oxygen produces an acid; and, lastly, the union of acids with alkalies, &c., gives rise to that very numerous and important class of substances called salts.

I. NON-METALLIC ELEMENTS.

Oxygen.

Oxygen gas occurs in a state of freedom in the atmosphere, of which it constitutes about one-fifth part by volume. In combination with other elementary substances, oxygen is present in water, sandstone, limestone, clay, and other rocks, as also in the materials derived from the vegetable and animal kingdoms. Indeed, it is probable that one-half of the entire globe is composed of free or combined oxygen.

The most modern method of preparing this gas is to prepare a mixture of four parts pulverised chlorate of potash, and one part binoxide of manganese; introduce the mixture into a retort (fig. 1), or a florence flask with

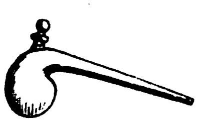


Fig. 1.

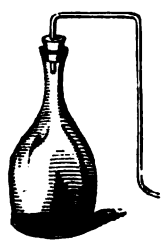

Fig. 2.

bent tube attached (fig. 2), support the vessel on a

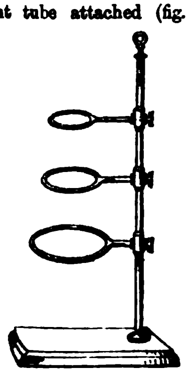

Fig. 3.

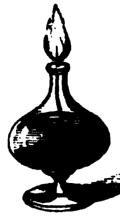

Fig. 4.

retort-stand (fig. 3), and apply heat from a gas-jet or spirit-lamp (fig. 4.) Oxygen is very readily given off, and may be collected by conveying the exit tube beneath jars filled with water and standing on the shelves of the pneumatic trough (fig. 5.) The gas may likewise be

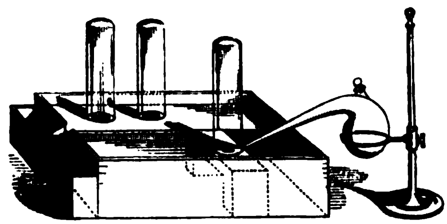

Fig. 5.

obtained from red oxide of mercury, nitrate of potash, chlorate of potash, or binoxide of manganese, taken separately. In the latter instances, however, a very high temperature is required, and accordingly the materials must be placed in an iron or fire-clay retort, and the heat of a furnace applied.

Oxygen is a colourless, odourless, and tasteless gas, which has never been liquefied nor solidified. It is slightly heavier than ordinary air, having the density of 1105·6 as compared with air taken as 1000. It is soluble in water to the extent of three volumes and a half in every 100 volumes of water. This gas is not combustible, but is a most powerful supporter of combustion; so that a candle, with simply a red wick, or a splinter of wood which has been on fire and then blown out, leaving a red tip, instantly bursts into full flame when plunged in oxygen, and thereafter burns with great rapidity. Sulphur, phosphorus, and even a spiral of iron wire or a watch-spring, ignited and surrounded by an atmosphere of oxygen, retained within proper vessels (figs. 6, 7 and 8), burn with dazzling

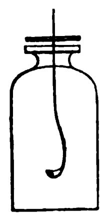

Fig. 6.

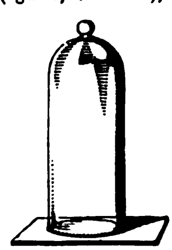

Fig. 7.

Fig. 8.

brilliancy. Indeed, it is the presence of this gas in the atmosphere that enables our gas-jets, candles, and coals to burn.

As an agent in respiration, oxygen is of vast importance. Animals inhale it from the atmosphere at every breath, and were they deprived of it for a few minutes, they would cease to live. At each inspiration, oxygen passes into the lungs, there meets the blood, in which it is dissolved, and carried into every nook and corner of the animal frame. There it supplies air to burn minute particles of fat, &c., and in this manner assists in keeping up the temperature of the animal system. Pure oxygen cannot, however, be inhaled for a length of time without alarming symptoms beginning to manifest themselves. After an hour or so, the breathing of the animal becomes more hurried, and the circulation of the blood more rapid. This period of excitement gives place to one of great debility, and death occurs in six to twelve hours.

Oxygen is essential to the germination of plants, and likewise to their growth. During the active and healthy growth of the vegetable kingdom, this gas is exhaled by them in large quantity; the same remark applies to sea-weeds and other plants growing in water.

Animals inhabiting the water are thus supplied with much of the oxygen they require, which, being dissolved in the water, passes through the gills, and from thence enters the system, and performs the same functions as in the case of the land animal.

The compounds of oxygen with other elementary substances are divided into three classes—*acid oxides*, such as sulphuric acid, a compound of sulphur and oxygen; *basic oxides*, such as *rust* (peroxide of iron), made up of iron and oxygen; and *neutral oxides*, such as water, composed of hydrogen and oxygen.

Ozone.—It has been long known to electricians that a peculiar odour accompanied the working of frictional electrical machines, but it is only recently that this odour has been recognised as pertaining to a distinct gas or air composed of three atoms of oxygen rolled into one. Besides being produced in the air contiguous to an electrical machine in active operation, it is likewise formed when a piece of phosphorus is placed in a jar of air and half covered by water. The production of this curious substance may be observed by suspending in the jar a slip of paper moistened with solution of iodide of potassium and starch, which is changed to a rose-red colour, and ultimately to a purplish violet. Another method of preparing ozone is to place a little ether in a jar, and thrust into the air, containing the ether vapour diffused through it, a heated glass-rod. Much heat will now be produced from the partial combustion of the ether, and the test-paper will indicate the production of ozone. Very little is known about the natural distribution and source of this gas, but it is generally present in the atmosphere, especially in winter. Much more is found in country districts than in towns, and this is accounted for by the rapidity with which ozone combines with and destroys any vegetable or animal matter in a state of putrefaction. So much is this the case, that a piece of bad-smelling meat, suspended in a jar containing the gas, very quickly loses all disagreeable odour. Ozone is, doubtless, therefore of great use in clearing away infectious and other organic matters from our atmosphere, and this it accomplishes from the great oxidising powers which it possesses. Another property which it exhibits in a marked degree is that of bleaching; and though, as yet, it has never been used in our bleach-works, yet it appears very probable that the present household process of bleaching—namely, by laying out and exposing the moistened cloth to the action of the sun and air—owes much of its efficacy to the presence of ozone in the atmosphere.

Hydrogen.

Hydrogen is found in an uncombined state in minute cavities in the rock-salt of Wieliczka; but the quantity so distributed is very small. It generally occurs chemically united with other elements, as in water, where the hydrogen is associated with oxygen. It is likewise present in coals, and the majority of substances derived from plants and animals.

The most convenient method of preparing the gas is to introduce into a bottle (fig. 9) a few fragments of zinc, some water, and a little sulphuric acid (oil of vitriol). The gas begins immediately to come away, and if a cork, with a bent glass or metal tube passing through it, be inserted in the bottle, the gas may be easily conveyed into jars filled with water, and standing on the pneumatic trough (fig. 5 or 10). In this experiment, iron filings may be substituted for the zinc, and hydrochloric acid for the sulphuric acid, provided such only be at hand.

Fig. 9.

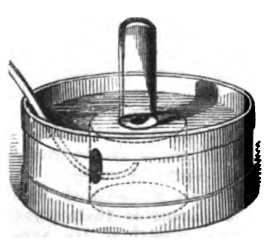

Fig. 10.

Hydrogen, when pure, is a colourless, tasteless, and odourless gas. When freshly prepared, however, it always possesses a peculiar odour, which is due to the presence of an oily compound of carbon and hydrogen. The pure gas dissolves in water to the extent of 1½ volumes in every 100 of water. It has never been liquefied nor solidified. It has the specific gravity of 69·2, air being taken as 1000, and oxygen 1105·6, and is consequently 14½ times lighter than air, and 16 times lighter than oxygen. This lightness of hydrogen may be observed by uncovering a jar containing it, when, in less than one minute, the gas will be found to have risen out of the vessel; or by filling a small balloon with hydrogen, when the former will rise to the roof, and remain there some time. Even soap-bells will rise and float through the air, when they are dexterously blown from a stream of this gas. Hydrogen is a combustible gas, burning with a pale-yellow flame, but it is a non-supporter of combustion, and will not allow a candle or any other light to burn in it. Though little light is evolved when hydrogen is burning, yet the heat given off is very great; so much so, that an arrangement called the oxyhydrogen blow-pipe, at the mouth of which hydrogen is burned with oxygen or air, produces the most intense heat known. During the ordinary combustion of hydrogen, it quietly combines with the oxygen of air, and produces pure water; but if the hydrogen is previously mixed with common air or pure oxygen, and then set fire to, a more or less violent explosion is the result. The proportions required to produce this explosive mixture are two volumes of hydrogen to one of oxygen.

By far the most important compound of hydrogen with any other substance is that with oxygen, forming the indispensable fluid which covers nearly two-thirds of our globe—*water*. Water is thus an oxide of hydrogen—a compound never found absolutely pure in nature. In the ocean it is salt and brackish, from the presence chiefly of chloride of sodium; in springs it is either carbonated—that is, contains carbonic acid; sulphureous, from the presence of sulphuretted hydrogen; chalybeate, from the union of the sulphate or carbonate of iron; and so on, according to the nature of the mineral ingredients through which it percolates. When it contains a chemical compound of lime, it is said to be *hard*, and in this condition it decomposes soap, and destroys its detergent properties. The impurity of water may thus arise either from chemical union or mechanical mixture with other bodies. The latter can generally be removed by filtration; but when the union is chemical, distillation (a process to be afterwards described) is necessary to produce a pure liquid.

Hydrogen also unites with the other supporters of combustion; but the compounds, except hydrochloric acid (to be afterwards mentioned), are not of any great importance.

Nitrogen.

This element occurs uncombined in the atmosphere to the extent of four-fifths of its entire bulk, and, chemically united with other substances, it exists in the native nitres, as also in plants and animals.

Nitrogen may be prepared by burning phosphorus in a confined portion of air, when the combustible abstracts the oxygen and leaves the nitrogen (fig. 11). This experiment is best accomplished under a bell-jar

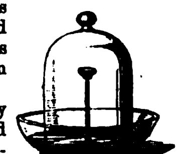

Fig. 11.

closed at the top, and the lower part open, but surrounded by water. As the oxygen disappears by uniting with the phosphorus, the water rises in the jar, till, when combustion has ceased, about four-fifths of the original bulk of air will be left as nitrogen.

This gas is colourless and transparent, without odour or taste. It has a specific gravity of 971·37, and has resisted all attempts at liquefaction or solidification. In the ordinary sense of the term, it is not combustible, neither does it support combustion. Consequently, a lighted candle is immediately extinguished when it is plunged into a jar of the gas (fig. 12). An animal immersed in nitrogen soon dies; not that it is a poison, but because, while the animal is inhaling this gas, it is debarred from inhaling oxygen, which is essential to life. The chief use of so much nitrogen being present in the air seems to be the dilution of the oxygen to that strength which is safe for the purposes of combustion and respiration. Nitrogen is less soluble in water than oxygen, and has no action on vegetable colours.

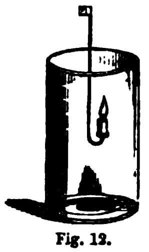

Fig. 12.

The atmosphere consists mainly of nitrogen and oxygen, in the proportion (if these ingredients be alone regarded) of 210 oxygen to 790 nitrogen, by measure; and of 231 to 769 by weight. Common atmospheric air alone, contains as constant ingredients in every situation, a little carbonic acid gas, vapour of water, ammonia, nitric acid, and ozone. In volume, the carbonic acid forms about 1-2000th part; or 0·5 parts in 1000 by measure; which is equal to 0·75 parts in 1000 by weight. Its proportion is greater in summer than in winter, during night than in the daytime, in elevated situations than on the plains. The watery vapour is more variable in proportion. The mean is supposed to be about 10 parts in 1000 by weight, 15 by volume. The quantity is determined by the temperature, heat being the sole cause which sustains the vapour in the aërial state. The free nitrogen and oxygen of the atmosphere are there merely as a mechanical mixture, and not as a chemical compound. The oxygen performs the chief part in the process of respiration, the nitrogen acting in a negative capacity as a simple diluent.

Nitrogen combines with the majority of the supporters of combustion. With oxygen it unites in no fewer than five proportions—namely, one equivalent of nitrogen to one, two, three, four, and five of oxygen respectively; or, one volume of nitrogen to a half, one, one and a half, two, and two and a half of oxygen. Of those compounds, by far the most important is nitric acid, or the *aquafortis* of the alchemists.

Nitric Acid occurs largely native in combination with potash, as nitrate of potash, or saltpetre; and with soda, as nitrate of soda or cubical nitre. It is likewise found to a minute extent in the atmosphere, and in spring-waters whose source is in the neighbourhood of church-

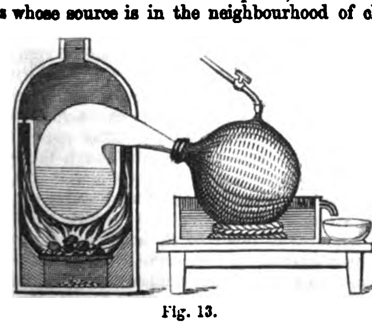

Fig. 13.

yards. It can be most economically prepared by placing equal weights of nitrate of soda and sulphuric acid in a retort (fig. 13), and applying heat. The nitric acid distils over, and is collected in a receiver surrounded by cold water. What is left in the bulb of the retort is the sulphate of soda, a compound of soda and sulphuric acid. Nitrate of potash may be substituted for the nitrate of soda in the above experiment. As thus prepared, nitric acid generally contains a little hydrochloric acid, sulphuric acid, and iodine, obtained from the salt employed.

When pure, nitric acid is colourless, with a peculiar odour, and an intensely sour taste even when diluted with much water. Subjected to bright light, a portion of the acid is decomposed, producing nitrous acid, which causes the remaining acid to assume a yellow tint. Exposed to the air, the strong acid fumes, from the union of the acid vapour with the water vapour of the air. The affinity of nitric acid for water is so great, that a bottle well filled with the acid, and left unstoppered, sucks in so much water from the air that it fills up and runs over. The commercial acid has a density of 1424, water being taken as 1000, contains two-fifths of its weight of water, and boils at 250° F. The strongest acid, or *double* aquafortis, holds one-seventh of its weight of water, has the specific gravity of 1522, and boils at 184° F. The latter strength is employed, along with sulphuric acid, in preparing *gun-cotton*. *Anhydrous nitric acid* has recently been produced by passing a stream of dry chlorine over dry nitrate of silver. It is thus obtained in the crystalline form, melts at 86° F., and boils at 113° to 122° F.

Nitric acid has very remarkable effects upon water with regard to the production of heat. If diluted with half its weight of water, heat is evolved; but if the water be in the state of snow, intense cold is the result. Hence this compound is employed to produce great degrees of cold. If nitric acid, highly concentrated, be thrown upon phosphorus, charcoal, or oil of turpentine, it inflames them. It is very extensively used in the arts, particularly for the purification of gold, for etching on copper-plates, &c.

Nitric acid forms a numerous and important class of salts, having the generic name of *Nitrates*—such as nitrate of silver, nitrate of potash, &c. Some of these we shall notice afterwards. *Nitrous acid* is a compound of the same kind as nitric acid, but with a lesser quantity of oxygen. Amongst the other compounds of nitrogen and oxygen, that entitled the *protoxide of azote*, or *nitrous oxide*, is the most remarkable. It is prepared by heating the nitrate of ammonia in a retort when the salt fuses, and then passes entirely into water and nitrous oxide. The latter is a colourless and transparent gas, with a slight agreeable odour, and a sweet and pleasant taste. Davy discovered that we may breathe it for a short while without any effect being produced, except an exhilaration of the mind; hence the term *laughing gas*, which is sometimes applied to it. Combustibles burn in it more brilliantly than in common air. Faraday has succeeded in solidifying this gas under a pressure of fifty atmospheres at 45°, and is of opinion that it might be employed in this state with greater advantage than solid carbonic acid, for producing intense cold by its evaporation *in vacuo* when mixed with ether. There is also a *nitric oxide* and a *hyponitrous acid;* but these do not require minute detail. Nitrogen combines likewise with chlorine and bromine.

Ammonia, or *Hartshorn*.—This important substance is formed by the combination of nitrogen with hydrogen, and is obtained in the state of gas from the salt called *sal ammoniac*, which is a compound of hydrochloric acid and ammonia. This substance is introduced into a retort, along with quicklime, and then subjected to heat. Ammonia is driven off in the form of gas, and is collected in glass jars standing over mercury. Ammoniacal gas is colourless, has a strong pungent smell, an acrid caustic taste, and cannot be drawn into the lungs.

Its specific gravity is 589. Water dissolves 780 times its volume of this gas, and the solution obtained by passing the gas into a vessel containing water, constitutes the commercial hartshorn, which is employed for chemical purposes and as an agent in our manufactures. When the gas is mixed with chlorine, a sudden combustion and detonation take place. The chlorine unites with the hydrogen of the ammonia, and forms hydrochloric acid, whilst the nitrogen is disengaged in the state of gas. The muriatic acid formed combines with a portion of ammonia, and forms sal ammoniac. Ammonia is an alkali, and possesses the properties distinguishing this class of substances in a very decided manner. It of course neutralises acids, and the salts which it forms are numerous, and of considerable importance.

Carbon.

Carbon occurs pure and free in the diamond, and combined with other elements in graphite (plumbago or black-lead), anthracite coal, ironstone, limestone, as also in the wood of all plants, and the fat and muscle of animals. It is prepared by burning wood, coal, &c., in close vessels. When wood is employed, the carbon is called *charcoal*, and when coal is the original material, the term *coke* is applied to the product. When bones are thus treated, they yield *ivory black*, *bone black*, or *animal charcoal;* and when oily substances are imperfectly burned, they produce much *lamp black*. Many varieties of carbon, especially the *bone black*, have the power of absorbing gases and coloured matters, and hence are useful in deodorising places where disagreeable smells are prevalent, and in clarifying and decolorising liquids—such as sirup of sugar. Carbon burns in oxygen with considerable brilliancy, although in common air it emits but a feeble light. If carbon be burned in a close vessel, filled with oxygen, the carbon will be entirely consumed, and the oxygen so much changed, that a lighted taper put into it is immediately extinguished. Carbon combines with all the supporters of combustion, and with oxygen forms carbonic acid.

Carbonic Acid, discovered by Black in 1757, and described by him under the name of *fixed air*, may be prepared at the pneumatic trough, by putting into a retort or bottle some chips of marble, or carbonate of lime, and an ounce of hydrochloric acid, previously mixed with two ounces of water. An effervescence takes place between the acid and the marble, carbonic acid gas being given off, which can be collected in jars. Carbonic acid is fatal to animal life, and the gas will extinguish a candle introduced into it. A candle cannot burn in a mixture of four measures of atmospheric air and one of carbonic acid; and no animal can live in air which contains sufficient carbonic acid to extinguish a candle; hence the practice of letting down a burning taper into old wells, pits, brewers' tuns, and the like, before any one ventures to descend. If the light is extinguished, the air is certainly impure; and there is generally thought to be no danger if the taper continues to burn; but instances have been known of the atmosphere being sufficiently loaded with carbonic acid to produce insensibility, and even death, and yet not so foul as to extinguish a candle. Water, under the ordinary pressure of the atmosphere, dissolves a certain amount of carbonic acid, and under pressure, may be saturated with it, in which state it sparkles when poured from one vessel to another. All kinds of spring and well water contain carbonic acid absorbed from the atmosphere, and to its presence they are partly indebted for their pleasant flavour. Boiling deprives water of its carbonic acid, whence its insipid taste. The agreeable pungency of beer, porter, ale, and many other beverages, is in a great measure owing to its presence; by the loss of which, on exposure to the air, they become flat and stale. Thus, though deleterious when breathed into the lungs, carbonic acid is exhilarating and wholesome when taken in moderate quantities into the stomach.

Carbonic Oxide is produced when carbonic acid is passed over red-hot charcoal, contained in an iron or porcelain tube. It is likewise formed in our grates, when carbonic acid, generated at the lower bars, rises through a stratum of red-hot coal. This change is evident from the blue flame of carbonic oxide, which is observed in our fireplaces, especially during frosty weather. It contains less oxygen than carbonic acid, but is even more poisonous.

Oxalic Acid is another well-known combination of carbon with oxygen, and may be formed by digesting sugar along with nitric acid. The acid is deposited in small crystals, which have an intensely acid taste, and when taken internally, even in small quantities, destroy life. It combines with bases, and forms a genus of salts called *oxalates*. Carbon is capable of uniting with chlorine in three different proportions, with bromine in one or two, and with iodine in two.

There are many combinations of carbon with hydrogen, and much uncertainty prevails both with regard to their number and nature; they are all designated *hydro-carbons*, or more properly *hydrocarburets:—Carburetted hydrogen*, or *marsh-gas*, a spontaneous production of nature in mines, &c., is one of the most terrific instruments of destruction, and a great obstacle to human industry; for, by mixing with a certain quantity of common air, it acquires the property of exploding when accidentally kindled, and thousands of human lives have fallen sacrifices to its violence, until Sir Humphry Davy's invention of the safety-lamp greatly divested it of its terrors. (See MINING.) Davy's safety-lamp consists of a common lamp surrounded with wire-gauze. On analysing the carburetted hydrogen, or fire-damp, Sir Humphry Davy found that it would not explode when mixed with less than six times, or with more than fourteen times, its volume of atmospheric air; that air rendered impure by the combustion of a candle will not explode fire-damp, though the candle will still burn for a time; and that if a candle be burnt in a close vessel, with small apertures only above and below the flame, no explosion will ensue. The flame within will be enlarged, but no explosion take place; and it was found that the gas usually generated in mines will not explode in a tube less than one-eighth of an inch in diameter.

Bicarburetted hydrogen is the chief, although not the most abundant ingredient in *coal-gas*, now so generally used for illumination; the other ingredients are carburetted hydrogen, hydrogen, and carbonic oxide. Coal-gas is made by introducing a quantity of bituminous coal into a large cylinder called a retort, shut at one end, and furnished with a mouthpiece at the other, for closing or opening it; there is also a tube for carrying off the gas and other products as they form. A quick strong heat is applied round the cylinder, and a vast quantity of gas, composed of the four ingredients just mentioned, is thus extricated, with tar and an ammoniacal liquor, both of which are condensed by passing through pipes immersed in cold water. There is a great difference in the relative proportions of the gases in the mixture, as also in the quantity of tar, according to the quality of the coal, and the mode of applying the heat. A slow heat gives much tar and little gas, and that little of a poor quality; a quick heat gives much gas, of good quality, and less tar. Owing to these and other causes, the illuminating power of coal-gas varies much. Before it is let through the conducting tubes for public consumption, it is well agitated in contact with a mixture of lime and water, or passed through strata of loosely strewed hydrate of lime: it is thus deprived of much of its smell, and also of some of its illuminating power. (See LIGHTING.) There are other less important compounds of carbon and hydrogen, and the whole correspond with the law of multiple combination already described. *Naphtha* and *naphthaline* are hydrocarburets; the former a

transparent volatile fluid, the latter a transparent volatile solid, which assumes the form of crystalline plates: both are obtained from coal-tar by distillation.

Cyanogen.—This substance is a gaseous compound of nitrogen and carbon—technically, a *bicarburet of nitrogen.* It burns with a purple flame, and destroys life on being breathed. Cyanogen unites with a variety of bodies, and forms many important compounds.

Boron.

The *borax* of commerce is a compound of boracic acid and soda, and is brought chiefly from Tibet and Tuscany, under the name of *tinkal.* Boracic acid is a compound of oxygen and boron, in the proportion of one atom of the latter to three of the former. Pure boron is an opaque brownish-olive powder, infusible, and not volatile at any temperature to which it has as yet been subjected. It neither dissolves in nor acts upon water. At about 600°, it takes fire, and combines with oxygen, forming

Boracic Acid.—This substance evinces the usual properties of an acid, but it is not a powerful one at ordinary temperatures. At high temperatures, however, it displaces the strongest of the other acids, and is exceedingly useful in fluxing out the baser metals from the nobler. When the acid is detached from borax, by vitriol being poured upon a strong hot solution of that compound, boracic acid exhibits itself in scaly crystals. It dissolves in rectified spirits, and if the solution be set on fire, it burns with a green flame. Borax itself, when heated, melts into a perfectly clear glass, which is the basis of some artificial gems of considerable beauty. Borax communicates its own fusible nature to other bodies; hence it is used as a flux. *Flux* is a general term made use of to denote any substance or mixture employed to assist the fusion of minerals. There are a considerable number of such bodies; the alkalies are those most generally used. Boracic acid is the only known compound of boron with oxygen. There has been no compound yet discovered of boron with either bromine or iodine, but it combines with chlorine, forming a gaseous acid, to which the name of *borochloric acid* has been given; and also with fluorine, forming

Fluoboric Acid, which exists in the gaseous state. It is colourless, has an exceedingly acid taste, and a smell similar to muriatic acid. It contains no water, but possesses a powerful affinity for that fluid, and is on that account sometimes used as a test of the presence of moisture in gases. Its specific gravity is 2·362; and it seems to consist of one atom of boron and three of fluorine.

Silicon or Silicium.

Quartz, or *Rock-crystal,* which constitutes so considerable a portion of the crust of the earth, consists essentially of a peculiar acid substance, called *silica,* or *silicic acid.* This substance is a compound of oxygen, with the element *silicon.* The latter was, till lately, supposed to be a brown powder, similar to boron; but recent researches, which are not yet completed, would lead to the belief that it is a bright white metal, somewhat similar to silver. When mixed with dry carbonate of potash, or soda, and heated far below redness, it burns vividly, at the expense of the carbonic acid; carbonic oxide is disengaged, and the residue is tinged black by carbon being deposited. By this process, silicon is converted into silica, which is a compound of one equivalent of silicon and three equivalents of oxygen. Silicic acid forms several important compounds, called *silicates,* with the fixed alkalies, and various metallic oxides. Every kind of ordinary glass is a silicate; the varieties (bottle, plate, flint, &c.) depending on the nature of the alkali or oxide, the proportions of the constituents, and the admixture of foreign matters.

Silicic acid or silica is the material most characteristic of the mineral kingdom. Imbedded in cavities in rocks, it is found in a pure condition as *rock-crystal.* With more or less of impurity, it forms jaspers, quartz rocks, flints, and sandstones; besides being a constituent of most rock-masses, such as granite and greenstone, as also clays and soils in general. It occurs in all spring-waters, especially those of the Geysers of Iceland. In the vegetable kingdom, silica is useful to such plants as wheat, enabling them to build up a more firm stem; and many of the lower animals have their outer casing or shell composed of this substance.

Silicon combines with chlorine, forming a *chloride of silicon.* This is a colourless volatile liquid, having a suffocating smell, and probably acid properties. With fluorine, silicon unites, and forms *Fluosilicic Acid,* which is a gaseous substance, transparent, colourless, and having a smell like muriatic acid. It smokes when mixed with moist air, and it is rapidly absorbed by water. Its specific gravity is 3·6.

Sulphur.

Sulphur, or brimstone, is found native in large quantity imbedded in the rocks of most volcanic districts, as on the flanks of Etna in Sicily, and Hecla in Iceland. Even volcanic ashes are more or less impregnated with sulphur. In the Sicilian mines, the sulphur is imbedded in masses of blue clay, which intermingle with it, and present an appearance as of marble. The earthy matter which thus accompanies the true sulphur veins, is separated from it by distillation when the sulphur is sublimed and condensed in proper receivers. Two varieties of this substance in a refined condition are known in commerce—namely, *roll sulphur,* prepared by pouring liquid sulphur into cylindrical wooden moulds; and *flowers of sulphur,* obtained by passing the vapour of boiling sulphur into a large cool chamber, where it rapidly condenses, and falls as a kind of *sulphur snow.*

The properties of sulphur are, that, when in mass, it is a pale, yellow, brittle solid; quite insipid and inodorous in the cold, but when heated or rubbed, acquires a peculiar odour. It is not soluble in water nor in alcohol, but is dissolved by turpentine, the fixed oils, and bisulphuret of carbon. The latter is its best solvent, and when warm, takes up about one-third its own weight of sulphur, which it deposits in greater part on cooling in the form of crystals. A roll of sulphur heated slightly, by being held in the palm of the hand, splits into pieces with a crackling noise, owing to the unequal expansion of its several parts. It is a non-conductor of electricity, and, when rubbed, becomes highly electric. It has a specific gravity of about 2. Its point of fusion is 232°; between 232° and 280° it possesses the highest degree of fluidity, is then of an amber colour, and if cast into cylindrical moulds, forms the common *roll sulphur* of commerce. It begins to thicken about 320°, and acquires a reddish tint; and at temperatures between 428° and 482° it becomes thick and highly tenacious. From 482° to its boiling-point it again becomes liquid, but never to the same extent as when at 248°. When heated to 430°, or thereby, and suddenly cooled, by being poured into water, it becomes a stringy and ductile mass, and may be used for taking impressions of seals, &c. It begins to rise slowly in vapour before it is completely fused, but at 792°, or thereby, it volatilises rapidly, its condensed fumes forming the fine powder known as the *flowers of sulphur.* Sulphur is extensively used in the arts; for instance, in the manufacture of gunpowder. With oxygen it combines in many proportions, forming compounds, all of which possess acid properties.

Sulphurous Acid.—When sulphur is heated to 300° in the open air, it takes fire, and burns with a pale-blue flame, at the same time emitting abundance of fumes of a suffocating nature, which are sulphurous acid.

A more convenient method of preparing the gas is to drench charcoal, shavings, straw, &c., with sulphuric acid, and apply heat, when sulphurous acid gas

(accompanied by carbonic acid) is evolved. Where pure gas is desired, copper or mercury should be substituted for the charcoal.

At ordinary temperatures, sulphurous acid is a colourless and transparent gas, with the peculiar and well-known odour of burning brimstone, and an acid taste. Its specific gravity is 2210. At 0° F., and surrounded by a freezing mixture of ice and salt, it becomes liquid; and placed under an air-pump in working order, and immersed in a freezing mixture of carbonic acid and ether, it becomes solid. Ordinary sulphurous acid is soluble in water to the extent of thirty times the volume of the water, producing a solution which possesses the marked odour of the gas, as likewise many other of its properties. The gas is not combustible, nor is it a supporter of combustion. To animals, it is quite irrespirable. The gas, and its solution in water, redden litmus, and possess great bleaching powers, as shewn in the rapidity with which it whitens coloured roses, red cabbage infusion, or woollen, silk, and straw goods. For the latter purposes, it is used on the large scale in the arts and manufactures. Sulphurous acid has likewise the property of arresting the decomposition of putrefying matter, and as a fumigating agent it has been used from time immemorial. It is composed of one equivalent of sulphur united with two equivalents of oxygen, and combines with bases such as soda to form a class of sulphites, of which sulphite of soda is an example.

Sulphuric Acid, or *Oil of Vitriol*, differs from the preceding acid in containing one half more oxygen. In its manufacture, two stages are observed in the process: *First*, The production of sulphurous acid, and *Second*, The oxidation of that body into sulphuric acid. The materials employed are—1. Sulphur, by the combustion of which sulphurous acid is produced; 2. Nitrate of soda, drenched with sulphuric acid to liberate the oxidising agent, nitric acid; 3. Air; and 4. Steam. The apparatus employed is a large leaden chamber, divided into compartments by lead curtains, having an oven connected with it, in which the more solid ingredients in the manufacture are placed, and a boiler to supply steam. When the gases and vapours enter the chamber, three of the sulphurous acid atoms attack the nitric acid, rob it of three of its equivalents of oxygen, convert themselves into molecules of sulphuric acid, which dissolve in the steam; whilst they leave the nitrogen of the nitric acid in combination with only two atoms of oxygen as nitric oxide. The latter substance, whenever it comes in contact with the oxygen of the air in the chamber, seizes two atoms more than it already possesses, and produces nitrous acid, which is again attacked by sulphurous acid. This process is repeated again and again, till the minute amount of nitric acid has oxidised a large amount of sulphurous acid. The oil of vitriol obtained at first has a specific gravity of 1·600, or less, and contains much water. It is concentrated by evaporation in lead basins, and subsequently in platinum retorts, when it acquires a density of 1·850. Sulphuric acid prepared in this manner is a colourless, oily liquid, which rapidly darkens in tint when dust or any carbonaceous matter gets access to the bottle. It is the acid of acids, having a most decided acid taste and action on colouring matters. It is one of the most powerfully corrosive substances known. When a bottle nearly filled with sulphuric acid is unstoppered, and exposed to the air, it absorbs moisture therefrom, the liquid increases in bulk, and ultimately runs over the side. The affinity of this acid is likewise noticed by pouring it into water, when much heat is evolved. Owing to the same property, its great affinity for, and consequent absorption of water, sulphuric acid readily chars wood, paper, and other organic substances, when these are immersed in it. The enormous quantities of this acid which are being constantly manufactured in this country for home use and exportation, have led to its being designated 'English oil of vitriol.' This variety retains one equivalent of water in combination with one of true acid. A more concentrated variety called *Nordhausen Sulphuric Acid*, prepared by heated, dry, and pulverised sulphate of iron in fire-clay retorts, from which it is distilled, contains only one of water to two equivalents of the real acid. This latter kind, when redistilled in dry vessels, yields crystals of *Anhydrous Sulphuric Acid*. The English oil of vitriol is very extensively employed by bleachers, dyers, calico-printers, &c. It forms a very numerous and important class of salts called *Sulphates*. The compounds of sulphur and oxygen—namely, the hyposulphurous and hyposulphuric acids—it is unnecessary to notice. Sulphur unites with chlorine in two proportions. It also combines with bromine, iodine, and fluorine, but its next most important combinations are those with hydrogen.

Sulphuretted Hydrogen, or *Hydrosulphuric Acid*.—This gas is present in, and is the cause of the fetid smell of rotten eggs. It is a constant accompaniment to the rotting of animal matter, being specially evolved from cesspools and sewers. It is likewise present in that class of mineral waters popularly called sulphureous. Sulphuretted hydrogen may be procured by placing sulphuret of iron, water, and sulphuric acid in a bottle with bent tubes, and collecting the gas evolved over hot water. It is colourless and transparent, with a disagreeable odour, and a sweetish taste. It is a non-supporter of combustion, and, when breathed, destroys animal life. Its specific gravity is 1175. It is combustible, and burns with a bluish-red flame. Water absorbs 2½ times its bulk of this gas; and if it be passed through water tinged with a vegetable blue, it will change the colour to red. A few drops of nitric acid let fall into a vessel filled with sulphuretted hydrogen, will set fire to it. This gas blackens silver, and the woodwork of rooms painted with white-lead are often tarnished, from human exhalations containing a portion of it. Its atomic constituents are one atom of sulphur and one atom of hydrogen.

Selenium.

This is a substance nearly allied to sulphur in its nature, although it in some respects partakes also of the character of a metal. It is associated with sulphur in its native state, and is often found in the sulphuric acid of England and the continent. It acts the same part as sulphur in mineral compounds. As prepared, selenium is a deep-red coloured powder, which becomes semi-fluid at 392°, fuses at 482°, and boils at 1292° F., evolving a vapour of a less yellow tint than that of sulphur. When heated to ignition, selenium gives off a very decided odour of horse-radish. It is a bad conductor of heat, a non-conductor of electricity, and is also non-electric. Like sulphur, it sublimes into flowers. The compounds of selenium and oxygen bear a strong analogy to some of those of oxygen with sulphur.

Phosphorus.

This substance is always found in a state of combination. It occurs to a small extent in granite and other rocks and minerals, and largely in the fossil guano called coprolites. It is likewise present in plants, especially those which are edible, and in animals of high organisation, forming one of the essential constituents of bones, blood, &c. In the preparation of phosphorus, bones are first calcined, to burn away organic matter, and the white *bone ash* left is ground to powder, and digested in dilute sulphuric acid. After subsidence, the liquid is decanted off, evaporated nearly to dryness, mixed with charcoal and sand, and heated in a fire-clay retort. The phosphorus is set free, and distils over by the neck of the retort, which, being immersed in cold water, admits of the phosphorus there condensing in pellets the size of a pea. These being collected, can readily be fused under hot water, and the liquid phosphorus so obtained run into moulds, from which, when cold, it is extracted in the form of sticks.

At ordinary temperatures, phosphorus is a solid of a

vary consistence and aspect. When newly prepared, it is soft, flexible, and translucent; but age makes it hard, brittle, and opaque. Its specific gravity is 1·770. Raised to a temperature of 108° F., it melts into a clear amber-coloured liquid: and at 550° it boils, giving off a vapour of the great density of 4350. In cooling, if kept at rest, phosphorus will remain liquid even at 40° F.; but the moment it is agitated, the whole is frozen. It is not soluble in water, but dissolves to a greater or less extent in alcohol, ether, fixed and volatile oils, as also in bisulphuret of carbon. The latter is its best solvent, as it takes up one-fifth of its own weight of phosphorus. Exposed to the air, uncovered by water, phosphorus emits an odour of garlic, and becomes luminous from a slow combustion or oxidation proceeding. Heat is thus evolved, and in a short time the mass fuses, and ultimately takes fire spontaneously, and burns with a vivid light. This combustion of phosphorus reaches a dazzling brilliancy when pure oxygen is the atmosphere in which it is burned.

Red Phosphorus, or *Amorphous Phosphorus*, is procured from ordinary phosphorus by enclosing dried chips of the latter in a vessel with little access to air, and kept for days at a temperature of about 440°. The amber-coloured liquid slowly changes into the same weight of a red powder. Should the temperature be raised to 482°, the red variety again returns to the state of ordinary phosphorus. The tint of the coloured variety is not constant, but ranges from a scarlet to a blackish brown. It has a specific gravity of 2·089 to 2·106; is insoluble in water, alcohol, ether, and bisulphuret of carbon; is not luminous in the dark; does not oxidate at ordinary temperatures, and therefore need not be kept under water, but burns when heated to 482°. The most remarkable difference between red and ordinary lies in the poisonous character of that in common use, and the *non*-poisonous property belonging to the red variety.

Phosphoric Acid is the substance produced during the combustion of phosphorus in air or pure oxygen. It may likewise be formed by acting on bone-ash (in greater part a compound of phosphoric acid and lime) by dilute sulphuric acid, which combines with the lime to form the comparatively insoluble sulphate of lime, whilst the phosphoric acid remains in solution. It is readily soluble in water, and forms a colourless and odourless liquid, possessing the usual characters of an acid. It has a sour taste, with a powerful corrosive action on the teeth, but little on animal and vegetable tissue in general. It neutralises bases such as lime, and forms three series of salts: 1. With one atom of base; 2. Two atoms of base; and 3. Three atoms of base. The proportions in which the constituents are present in the phosphoric acid is, one equivalent of phosphorus to five equivalents of oxygen. There are other compounds of phosphorus and oxygen containing less oxygen than phosphoric acid does, but these are not of much importance.

Phosphuretted Hydrogen, *Ignes Fatui*, *Will-o'-the-wisp*, or *Jack-o'-lantern*, is naturally emitted from boggy places and grave-yards, and has been long known and feared for its phantom appearance. It may be prepared by placing in a retort some hot water, a piece of phosphorus, and a little potash. Heat should be at once applied to the bulb, and the extremity of the neck of the retort plunged underneath a stratum of water. The gas immediately begins to come off, continues to explode with the air in the retort till that is exhausted, chases the spent gases out, and then gurgling through the water of the receiving-basin, bursts spontaneously into full flame when it escapes into the atmosphere. Phosphuretted hydrogen is a colourless gas, with a garlic smell, and a bitter taste. When mixed with oxygen, *rarefaction* causes them to explode, as *condensation* produces explosion in other gases—a very remarkable property of this substance. This gas may be detonated also with protoxide and deutoxide of nitrogen. When mixed with chlorine gas, it burns with a greenish-yellow flame. It is composed of equal volumes of hydrogen and phosphorus vapour. There are other compounds formed of these two substances: phosphorus combines also with chlorine, bromine, and iodine, in two proportions each; and unites with fluorine, carbon, sulphur, and selenium.

Chlorine.

The principal source of chlorine is common salt (a compound of chlorine and sodium), which occurs largely in many parts of the world as a rocky mass, called *rock-salt*, as also dissolved in the ocean and many spring-waters.

The most convenient method of preparing chlorine gas is to introduce into a retort, or flask with bent tube, some hydrochloric acid, with a little powdered peroxide of manganese, and apply heat. The gas readily comes away, and may be collected in the ordinary way at the pneumatic trough, or by allowing the gas to descend into dry bottles (fig. 14). A more economical process, and one

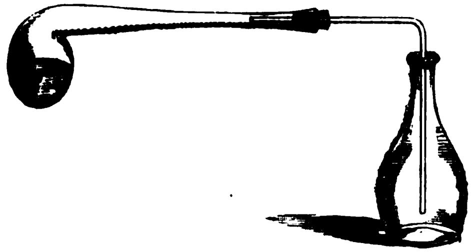

Fig. 14.

followed on the large scale, is to employ eight parts of common salt, six parts of peroxide of manganese, and thirteen parts of oil of vitriol. A complicated reaction ensues, and chlorine is given off.

The properties of the gas are, that it has a yellowish-green colour, a powerful suffocating odour, and a strong astringent taste. It is not combustible, and is only a partial supporter of combustion, as shewn by placing a lighted candle in the gas, when the hydrogen of the candle alone burns, and sets free the carbon as smoke or soot. Many metals, however, such as copper, antimony, arsenic, Dutch leaf, &c., in thin leaves or fine division, burn readily when introduced into chlorine, and combine with it, forming *chlorides*. An atmosphere containing much of this gas cannot be inspired without dangerous effects on the animal system; but when a very small quantity is present, as in the vicinity of bleaching-works, it becomes rather pleasant. It has a specific gravity of 2470, and has been liquefied under the

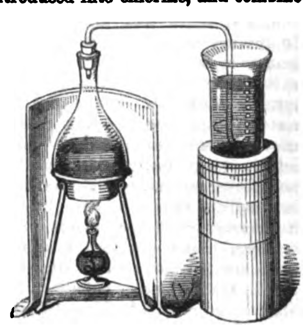

Fig. 15.

combined effects of cold and pressure. It is readily soluble in water (fig. 15), and then yields *chlorine water*, which possesses the same colour, odour, and taste as the gas itself. Both the gas and its solution in water possess the power of destroying all vegetable colours, and of rendering vegetable bodies exposed to their action white. This property has occasioned the introduction of chlorine, combined with lime, into bleaching; for if unbleached linens or cottons be exposed to its action, the matter which gives them their gray colour is destroyed, and the substance assumes a brilliant whiteness. Chlorine, however, must be used cautiously; for if applied in its pure,

and not sufficiently diluted state, it destroys the fibre of the cloth. It is also used in fumigation, being destructive of effluvia and infectious matters arising from putrefaction, disease, &c. Chlorine combines with oxygen in four different proportions: two of them contain so much oxygen as to form acids; these are chloric acid and perchloric acid; but as the other two do not manifest any acid properties, they are to be considered as oxides, and are called protoxide of chlorine and peroxide of chlorine. Besides uniting with oxygen, chlorine combines with hydrogen, and forms the well-known acid called

Muriatic or *Hydrochloric Acid.*—If chlorine and hydrogen be mixed together in equal volumes, and exposed to common daylight in a glass flask, they will in a little time combine, and even explode in combining if exposed to sunlight or the light of a candle. Hydrochloric acid gas may be more readily prepared, by placing in a retort equal weights of common salt and sulphuric acid, and applying heat. The gas is quickly evolved, and may be received in jars at the mercury trough, or in dry bottles. Its specific gravity is 1269. In its pure state, this gas is transparent, colourless, and elastic; under very strong pressure it condenses into a liquid. Water absorbs this gas with such avidity that one cubic inch absorbs 418 cubic inches of the gas, and forms the ordinary hydrochloric or muriatic acid. With these proportions of constituents, its specific gravity is 1210; one hundred grains of it consist of 42 of real acid, and 58 of water. It is a colourless liquid; and when exposed to the air, it smokes, because the gas exhaled condenses the moisture of the atmosphere. It extinguishes both flame and life, and is not inflammable. It has a pungent, suffocating, and somewhat aromatic smell, and powerfully reddens vegetable blues. An immense number of salts are formed from the combination of hydrochloric acid with oxides: such as common sea-salt, which is a muriate of soda, or chloride of sodium. These are very extensively used, both in the arts and medicine. Chlorine combines with nitrogen, and forms what is called

Chloride of Nitrogen.—This is an oily liquid, and the most powerfully explosive compound known. It consists of four volumes of chlorine combined with one of nitrogen.

Bromine.

Bromine is usually extracted from *bittern*—that is, the uncrystallisable residue left after chloride of sodium (common salt) has been extracted from sea-water. It appears to be an essential ingredient of the saline matter of the ocean, and is found in all its waters, as well as in most of the plants and animals which inhabit them. It occurs also in many springs. It resembles chlorine in many of its habitudes; at common temperatures, it is a liquid of a brownish-red colour, very disagreeable smell, sharp, strong taste, powerfully corrosive of organic bodies; and when taken internally, a violent poison. Its specific gravity is 2·976; it destroys vegetable colours almost as powerfully as chlorine. Like chlorine, it sets fire to certain metals when brought into contact with it; it is not combustible, and it extinguishes combustion; it becomes solid at a little below zero; but if combined with water, so as to form a hydrate, it affords fine red crystals at 32°.

An acid is formed by the combination of bromine with oxygen, and is called bromic acid; another with hydrogen is called hydrobromic acid.

Iodine.

This substance is derivable from sea-plants, and in some of its properties much resembles chlorine, which is also a marine production. It occurs in sea-water and many spring and river waters, some minerals, the majority of sea-weeds and land-plants, as also in marine and land animals. It is generally prepared from sea-weeds, which are collected, dried on the beach, burned, and the ashes treated with water, which dissolves out the compound of iodine. The solution so obtained is placed in a retort, treated with sulphuric acid and binoxide of manganese, and heat applied. The iodine sublimes, and is deposited in the cool receiver in the form of small bluish-black scaly crystals with a metallic lustre. These can readily be purified by resublimation. Iodine has a specific gravity of 4·948, fuses at 225°, and boils at 347°, when it rapidly volatilises as a splendid violet-coloured gas, with the high density of 8716. In the crystalline condition, it is very sparingly soluble in water, but is readily dissolved by alcohol, ether, alkaline iodides, and water containing a few iron filings. Its smell is disagreeable, its taste acrid and hot, and it possesses poisonous properties. It is a powerful stimulant, and has been employed as a medicine. It destroys vegetable colours, but not so completely as chlorine. It forms a beautiful blue colour when mingled with water holding starch in solution. Iodine combines with oxygen, forming iodic acid. A compound of iodine and nitrogen is exceedingly explosive.

Fluorine.

The existence of this substance, strange to say, is conjectural; yet its separate identity is supported by the strongest analogies. It exists in fluor, or Derbyshire spar, and is thus called fluorine. If some of this mineral in powder be distilled with strong sulphuric acid, from a leaden retort into a leaden receiver, kept cold with ice, an intensely active fluid is produced. 'It has,' says Davy, 'the appearance of sulphuric acid, but it is much more volatile. When applied to the skin, it instantly disorganises it, and produces very painful wounds. When it is dropped into water, a hissing noise is produced, with much heat, and an acid fluid is formed.' This substance has been called *hydrofluoric acid*, because it is conjectured to have fluorine as a base, combined with hydrogen, to form an acid, upon the principle which we have formerly described. The diluted solution, or the vapour of hydrofluoric acid, acts energetically on glass, and is employed for the purpose of *etching* on this material. (See No. 21.)

II. METALLIC ELEMENTS.

Metals of the Alkalies.

Potassium is the metal present in that well-known and very useful article potash. The properties of potassium were first determined by Davy in 1807, to whom we are indebted for the discovery of the composition of the alkaline bodies. It is a white metal, like silver, with a shade of blue. At 32° it is hard and brittle, at 50° is soft and malleable, at 136° melts, and at a low red heat evaporates. Its specific gravity at 60° is ·865, being lighter than water. When exposed to the air, it rapidly absorbs oxygen, and forms potash. This latter body, as found in commerce, is always combined with water, which cannot be expelled by heat. When potassium is thrown on the surface of water, upon which it swims, it decomposes that fluid with such rapidity that the metal takes fire, and burns (along with the hydrogen evolved) with a violet-tinted flame. The protohydrate of potassa, which is solid at common temperatures, is employed in surgery as a caustic, under the name of *potassa fusa:* it destroys all animal textures.

Sodium is a metal so similar in most respects to the foregoing, as to stand in no need of particular description. It is the metal present in the alkali called soda, which is formed when the metal is brought into contact with water, or when it is heated in oxygen. Sodium decomposes water, and in its relations to other bodies bears a strong resemblance to potassium. The uses of soda are well known, as are those of common salt, which is chloride of sodium. Sulphuret of sodium was lately discovered to be the colouring principle of the *lapis lazuli*, and since then has been used in the preparation of artificial ultramarine, the finer specimens of which are quite equal to the natural product, and much less

expensive. Sodium, which was discovered after potassium in 1807, is called *Natrium* by the German chemists.

Lithium is the metal of the alkali called lithia, which is of a white colour, and has a taste fully as caustic as that of potash itself. It is of course an oxide of lithium.

Metals of the Alkaline Earths.

Barium is the metal found in *barytes* or *heavy spar*, an alkaline earth, which is so named from its great density; *barys*, heavy. It is of a yellow appearance, absorbing oxygen rapidly by exposure to the air, thus forming barytes; and it also rapidly decomposes water.

Strontium.—This metal is present in strontia, an earth very similar to the foregoing. Strontium and barium, both discovered by Davy, resemble each other very much in most of their properties, and their combinations with oxygen have also a very strong resemblance. Strontium was originally extracted from strontianite, native carbonate of strontia, a mineral found at Strontian, in Scotland; hence the name *strontites*, or *strontia*.

Calcium is the basis of the well-known and indispensable commodity lime. *Lime* (*calx*) has been known from the remotest ages, and appears always in combination with an acid, most commonly with the carbonic, constituting *limestone*, *marble*, *calcareous spar*, *chalk*, and frequently with sulphuric acid, constituting *gypsum*, *selenite*, and *sulphate of lime*. It combines also with various other acids. Calcium is yellow, like gold, solid, and much heavier than water. When heated in the open air, it burns brilliantly, and quicklime is produced. Calcium unites with oxygen in two proportions, forming lime and peroxide of calcium. Pure lime has an acrid taste, and is sparingly soluble in water. It, however, readily absorbs water poured upon it, and swells, producing at the same time a great heat. The fact is, that the water becomes solidified, and of course gives out a great quantity of heat, which partly accounts for the rise of the temperature. This process is called slaking lime. Lime combines with chlorine, and forms *chloride of lime*—a substance which has become an important article of commerce, under the name of *bleaching-powder*. It is a white powder, with a hot taste, having the power of destroying vegetable colours.

Magnesium.—This metal is the basis of magnesia, a substance universally known from its frequent employment in medicine. Magnesium is obtained by the electrolytic decomposition of chloride of magnesium; and in common with barium, calcium, and strontium, it has been lately isolated, and its properties determined, by Dr Matthiessen of Heidelberg. It burns with a red light, and combining with oxygen, becomes *magnesia*. This is a soft, elastic, tasteless powder, not sensibly soluble in water, and slowly changing vegetable blues to green.

Metals of the Earths.

This family comprehends five substances, the oxides of which are white tasteless powders, distinguished by the name of *earths*.

Aluminum.—Alumina, which, when pure, is a fine light powder of brilliant whiteness, is an essential constituent in every kind of clay, and constitutes the base of *alum*, from which substance it may easily be obtained. It is a compound of oxygen and aluminum, consisting of two parts of the former to three of the latter. This metal, when burnished, assumes a metallic lustre resembling that of tin. It is not easily fused; but at a red heat it burns with great splendour, and is converted into alumina. This substance, so useful in the manufacture of every species of pottery, is the only compound known of oxygen with aluminum. Alumina possesses the remarkable property of shrinking into less bulk, according to the intensity of the heat which is applied to it; hence it was employed by Wedgewood as a kind of thermometer, or rather *pyrometer*, for measuring very high degrees of temperature, in furnaces for instance. A gauge is used for measuring the amount of the contraction.

Beryllium, or *Glucinium.*—Berylla, which is the oxide of beryllium, exists to about 14 per cent. in the beryl or emerald, from which it can be extracted. Beryllium is a dark-gray powder, which, when burnished, acquires the metallic lustre.

Yttrium.—Yttria, which constitutes the oxide of this metal, is obtained from a scarce mineral called *gadolinite*, found at Ytterby, in Sweden. Yttrium is procured from it in iron-gray scales. Mosander asserts the existence of two closely allied metals, which he calls *Erbium* and *Terbium*, also from Ytterby.

Zirconium.—The earth called zirconia is a harsh whitish powder, destitute of taste or smell. Zirconium is obtained in brilliant scales, which, when burnished, acquire the metallic lustre. Svanberg's experiments have rendered probable the existence of a closely allied metal, which he calls *Norium*.

Thorium, is a metal of a leaden-gray colour, heavy, and, under the burnisher, shews metallic lustre.

Chromium is a metal of a whitish colour and brittle consistency. Its specific gravity is 5·900. It is only obtained pure in small grains. Chromium combines with two proportions of oxygen, forming two compounds, the *green oxide* and *chromic acid*. It is used in coloured glass-making, and glass and porcelain painting. It is also employed in enamelling, and as a pigment. To glass and enamel it communicates a green colour, but to the painter it affords one of his prettiest yellows. Chrome red is the bichromate of potassa, and chrome yellow is the chromate of lead.

Metals Proper.

Iron.—This well-known substance is one of the seven metals with which the ancients were acquainted; these were gold, silver, copper, iron, tin, lead, and mercury. Iron is a metal of great utility, and it is fortunately found abundantly. Almost every mineral contains it. The ore from which the iron of Great Britain is chiefly obtained is a *carbonate of iron*. Iron, after passing through a fiery ordeal, has a grayish colour, a metallic lustre, and when burnished, a good deal of brilliancy. Its hardness exceeds that of most metals; and when in the state of steel, it may be rendered harder than most bodies. Its specific gravity is 7·843 after hammering. It is attracted by the magnet, and may itself be converted into a permanent magnet. It is malleable at every temperature, very ductile, and very combustible, for we see a thin wire burn in the flame of a common candle. It burns brilliantly in oxygen, with which it combines in two proportions, forming oxides, or *rusts*. The most important of its combinations with simple substances are those with carbon, which form the important compounds *cast iron*, *steel*, and *plumbago*. Iron forms with the acids a numerous and valuable class of salts. (See METALLURGY.)

Manganese.—When this substance is pure, which is rarely the case, it is rather whiter than cast iron, of a granular texture, and may be reduced to powder by pounding. Its specific gravity is 8·013. It is attracted by the magnet, only at a very low temperature. It gradually absorbs oxygen from the atmosphere, and decomposes water, a property which it loses when alloyed with iron. It is much in use. Glass-makers use it for two purposes; first, for communicating a purple or violet colour, or for destroying all colour, and rendering the glass colourless. Manganese has a strong affinity for oxygen, with which it combines in seven proportions, forming acids and oxides.

Nickel.—This metal, when pure, has a white colour, like silver; is rather softer than iron; is malleable both hot and cold; is attracted by the magnet; and, like iron, can be converted into one. Its specific gravity is 8·380 after fusion. The preparations of this metal contain poisonous qualities. Nickel combines readily with oxygen, forming two oxides. Nickel is chiefly derived from a copper-coloured mineral found in Westphalia, called

kupfernickel; nickel being an epithet of detraction, because the ore looked like copper, and yet none could be extracted from it. Nickel is a principal ingredient in the alloy called German silver.

Cobalt.—This metal has a gray colour, with a shade of red, and is not brilliant. Its texture is granular; it is rather soft and brittle; its specific gravity is 8·700. It is used for giving a blue colour to glass and porcelain; the tint is beautiful, and hence the metal bears a high price. It unites with oxygen, and forms two oxides; these are the preparations of cobalt used in the arts. Its name is derived from *kobold*, an evil spirit, because the German miners, at a time when they were ignorant of its value, considered it unfavourable to the presence of more valuable metals.

Zinc.—This metal is of a bluish-white colour, and is composed of plates adhering together. It is a hard metal, being acted on by the file with difficulty; and after fusion, its specific gravity is 6·896. It becomes malleable at 212°, and melts at 773°, or before it is quite red. When heated red-hot with access of air, it takes fire, burns with an exceedingly beautiful greenish or bluish-white flame, and is at the same time converted into the only oxide of zinc with which we are acquainted. It is of a snow-white colour, is tasteless, and insoluble in water. With copper, zinc forms that well-known and useful alloy called *brass.*

Cadmium.—This metal, which is commonly associated with the ores of zinc, has a white colour, with a shade of bluish-gray, and resembles tin in its appearance. It is very malleable, and has a specific gravity after fusion of 8·604.

Tin possesses a fine white colour, and has a good deal of brilliancy. Its specific gravity after fusion is 7·285. It is very malleable. Tin-leaf, or *tinfoil*, as it is called, is about the one-thousandth part of an inch thick, and it might be made much thinner if requisite. It is ductile, but of inferior tenacity. It is very flexible, and produces a remarkable crackling noise when bended. It melts at 442°; but a very violent heat is required before it will volatilise. It slowly tarnishes with the air, and when intensely heated, oxygen being supplied, it burns with great brilliancy. Tin combines with oxygen in three proportions, forming the protoxide, which is *black*, the sesquioxide, which is *grayish*, and the peroxide, which is *yellow*. It alloys with various metals. It is used in coating vessels, either in a pure state or alloyed. Pewter is composed of lead and tin; the latter rendering the former, a poisonous metal, quite innocuous.

Arsenic.—The *white arsenic* of commerce is a combination of this metal and oxygen. When mixed with *black flux* (cream of tartar, heated to redness in a covered crucible), and subjected to heat, it is reduced to the metallic state. It has a bluish-white colour, is soft, brittle, and easily reduced to fine powder. Its specific gravity is 5·672. When moderately heated, it volatilises, combining with oxygen, and forming the arsenic of commerce, so well known for its destructiveness to animal life. With oxygen, arsenic forms two acids—the *arsenious* and *arsenic*. *Arsenious acid* is a white, brittle, compact substance, having a weak, acrid taste, which at last leaves an impression of sweetness. It is one of the most virulent poisons known. *Arsenic acid* is quite similar in its constitution to phosphoric acid.

Antimony, which was discovered by Basil Valentine in 1490, possesses, when pure, a white colour, with a shade of blue. Its texture is fibrous, and it is easily reduced to powder by being pounded in a mortar. Its specific gravity is 6·800. It melts when heated nearly to redness, and at a higher heat it is sublimated in white fumes. It combines with oxygen in three proportions, and forms three compounds, two of which possess acid properties. The other is an oxide, which constitutes the base of all the active medicinal preparations of this metal. With chlorine it combines in two proportions, forming two chlorides, which are analogous to two of the compounds formed with oxygen. Antimony is extensively used in the arts, particularly in typefounding, stereotyping, and the manufacture of the white-metal utensils now so generally used as substitutes for silver.

Tellurium is a metal, having a silver-white colour, and considerable brilliancy. *Vanadium* is a whitish metal resembling silver, brittle, and is easily dissolved in nitric acid. *Uranium* is a metal of a white colour, of considerable lustre, and when heated to redness, takes fire. It produces a deep-green protoxide, which gives a black colour to porcelain, and a fawn-coloured peroxide, which communicates to porcelain an orange colour. Its specific gravity is 9·000. *Molybdenum* has a silvery white colour, is brittle, and has a specific gravity of 8·6. *Tungsten* is of a grayish-white colour, is very hard and heavy, having a specific gravity of 17·6. *Columbium*, when burnished, assumes a yellowish-white colour and a metallic lustre. *Titanium* has a white colour, and considerable brilliancy. *Cerium* exists in a reddish-coloured mineral found in Sweden, called *cerite*. *Lantanium* and *Didymium* may also be ranked under this family.

Lead.—This is one of the most abundant of all the metals, and one of the softest and most fusible. Lead has a bluish-white colour, and a good deal of lustre; but it soon tarnishes. Its specific gravity after fusion, which takes place at 606°, is 11·45. Lead is very malleable; it is also ductile, but its wire possesses little tenacity. By exposure to a very strong heat, it is volatilised, and at the heat of burning hydrogen, urged by oxygen, it burns with a bluish flame. While exposed to the atmosphere during fusion, it imbibes oxygen, and is converted into an oxide. There are three oxides of lead—the protoxide, which is known in commerce and the arts as a yellow paint, under the name *massicot*, or, if it be semi-vitrified, *litharge;* the deutoxide is also a paint of a brilliant red colour, inclining to orange—it obtains the name of *minium*, or *red-lead;* and the peroxide, which is of a deep puce *brown* colour. Lead is rendered hard by antimony; and the alloy mixed with a little tin, constitutes the material from which printers' types are elaborated. The salts of lead are numerous, and very important. *White-lead*, or *ceruse*, the only white used in all oil-paintings, is made by subjecting thin plates of lead, rolled up spirally, to the fumes of vinegar, and afterwards to carbonic acid exhalations. The lead soon becomes corroded, and assumes a white appearance and a brittle consistency. If this substance be dissolved in acetic acid, or vinegar, it becomes *sugar of lead*. Lead is never found native; by far the most common state in which it occurs is sulphuret of lead, or *galena*.

Copper, in point of general utility, ranks next to iron. It possesses a red colour, and a great degree of brilliancy. Its specific gravity, after being rolled out into plates, is 8·960. It has great malleability, and very considerable ductility. A bar of cast copper, one quarter of an inch thick, requires 1192 pounds to break it, whilst hammered copper requires nearly 1000 pounds more to break it. It melts at 1996°; and if the heat be increased, it evaporates in fumes, which are visible. When rubbed, it emits a smell. When heated in a hydrogen flame urged by oxygen, it burns brilliantly, emitting a dazzling green light; a piece of copper in a coal-fire tinges the blaze green. When exposed to air and moisture, it changes into a green carbonate of copper on the surface. With oxygen it combines in three proportions, forming three oxides, two of which occur native; the other is not a permanent compound. Its alloys with tin are very important, forming *bronze, bell-metal*, and other alloys.

Bismuth has a reddish-white colour, and is composed of broad plates adhering to each other. It is one of the most fusible of the metals, melting at 476°; it communicates its fusibility to other metals; hence its use as a *flux* and *solder*. Its specific gravity is 9·9. Although

not very brittle, it is not malleable, unless when heated, nor can it be drawn into wire. A mixture of tin, lead, and bismuth is so fusible that it melts when thrown into boiling water. A toy of this kind is well known; it is a spoon, which, when immersed in a very hot liquid, immediately melts. What is called Newton's fusible metal, is a compound of eight parts by weight of bismuth, five of lead, and three of tin; it melts at 212°. The nitrate of bismuth furnishes the medicinal powder called *pearl white* when it is thrown into water.

Mercury, or *Quicksilver*.—This metal has a silver-white colour, possesses great brilliancy, and remains fluid at the common temperature of the atmosphere. Its specific gravity at 60° is 13·59; at 39° below zero, when it assumes the solid form, it is 14·. When solid, it may be beaten out with a hammer, or cut with a knife. When heated to 662°, it boils; and when heated in the open air, it oxidises. The oxides and chlorides of mercury afford an admirable proof of the truth of the atomic theory. The alloys which mercury forms with the other metals are usually termed amalgams. This metal occurs in South America, California, and in Spain, in great abundance; but the mine of Idria, in Carniola, is perhaps the greatest in the world, and has been wrought for more than three centuries.

Silver.—This metal is of a fine white colour, with a slight shade of yellow. When polished, it displays a great deal of brilliancy and beauty. It is very malleable, and may be beaten out into leaves so thin as 1-100,000th of an inch. It is softer than copper, and harder than gold; but its tenacity is inferior to the former metal. When melted and cooled slowly, its specific gravity is 10·5; when hammered and rolled, it is a little higher. Its melting-point is 1873°; and if it be kept melted for a long time, it absorbs oxygen; but possesses the very singular property of parting with the oxygen on solidifying. The presence of a little copper deprives it of this property. Silver forms with oxygen only one well-known oxide. It also unites with chlorine, bromine, sulphur, arsenic, &c. There are numerous alloys of silver, but few of much consequence. Silver is found in all parts of the world, sometimes associated with a variety of other metals and substances as an ore, and sometimes in the native state.

Gold, the most valuable of all the metals, always occurs in nature in the metallic state, although seldom pure. It has a beautiful yellow colour, and considerable lustre, which it retains, not being liable to be tarnished by exposure to the air. It is rather softer than silver, and after fusion it has a specific gravity of 19·5. It is the most malleable of metals, and may be beaten out into leaves no thicker than 1-282,000th of an inch; and the goldleaf with which silver wire is covered is only one-twelfth of that thickness. Its tenacity is considerable, but inferior to that of silver. It melts at 2016°. It is insoluble in sulphuric, nitric, and hydrochloric acid; but it readily dissolves in aqua regia, which is a compound of the two latter. It is difficult to oxidise gold, and still more to burn it; but both can be accomplished. Oxygen combines with gold in two proportions, forming oxides. There are a number of alloys of gold; the standard gold coin of the realm is an alloy of eleven parts of gold to one of copper.

Platinum.—This metal is white, like silver. Its specific gravity is 21·5, and its hardness is intermediate between copper and iron. It is very ductile and malleable, though much less so than gold. Its tenacity is considerable. It will not melt in the heat of our most powerful furnaces, but it may be fused by the oxyhydrogen blow-pipe. On this account, as well as its property of resisting the action of most chemical agents, it has been employed in the formation of vessels which it is necessary to subject to an extraordinary degree of heat. Like gold, it resists the action of all the single acids, but dissolves in aqua regia. There is a form of this metal which possesses extraordinary properties; it is called *spongy platinum*. It is prepared by dissolving platinum in a mixture of nitric and hydrochloric acids by heat; chloride of ammonium is added, when a precipitate falls, which must be filtered and dried. If a jet of hydrogen, from a tube of a very slender bore, be directed on this powder from a little distance, the metal immediately becomes red-hot, and it sets fire to the hydrogen. This may be repeated a great number of times.

Palladium, Rhodium, Iridium, Osmium, and Ruthenium.—These five metals occur in the platinum of commerce. They are procurable in very small quantities.

Such is a brief sketch of the sixty-two simple substances whose numerous combinations give rise to the infinite variety of objects which are found ready formed in the laboratory of nature, or have been discovered in that of the philosopher. The minerals and metals of commerce will be further treated under the heads MINING and METALLURGY.

ORGANIC CHEMISTRY.

Vitality enables plants and animals to absorb and assimilate food, consisting of the elements necessary for their increase, and also to reproduce beings of their own kind, by means of certain organs; hence they are said to be *organised*, and the substances of which they are composed are known by the general name of *organic matter*. Earths, minerals, metals, and the like, not possessing vitality, have no organs, and consist only of *inorganic matter*. Organic chemistry—in contradistinction to Inorganic chemistry—is therefore that department of the science which treats of the composition, properties, and uses, as well as of the origin, of all substances produced in the animal and vegetable kingdoms, and of the artificial compounds arising from their decomposition. The chemist finds, however, so far as the ultimate analysis of organic substances can shew, that plants and animals are composed of the same elements as inorganic matter; and that the two branches of the science are not essentially different, so far as the nature of these elements is concerned. There is this peculiarity, however, that a certain class of organic compounds possess the property of uniting with the elements, and of forming with them new combinations, which are analogous in their properties to the combinations of two simple bodies. Such compounds are called 'compound radicals;' hence the term *chemistry of compound radicals*.

VEGETABLE COMPOUNDS.

Notwithstanding the infinite diversity of form which vegetable substances assume, it has been proved that they are all mainly composed of the same elements, and these are only *four* in number—namely, oxygen, hydrogen, carbon, and nitrogen. These, again, by uniting amongst themselves, form many of the compounds which constitute the vegetable structure; and these compounds being the more immediate objects of sense in the investigation of any organisation, are called their *proximate principles*. Existing ready formed in roots, woods, barks, leaves, flowers, fruits, and seeds, we find a considerable number of proximate principles, in the form of acids, alkalies, sweet principles, bitter principles, oils, exudations; some poisonous, others wholesome; some spontaneously separating, others remaining obstinately combined. We shall give a brief outline of these, referring for further details to VEGETABLE PHYSIOLOGY, AGRICULTURE, ALIMENTARY SUBSTANCES, AND MEDICINE.

Common *Citric Acid* exists in the juice of lemons, and when crystallised, one hundred grains consist of—water 23⅝, and pure acid 76⅜, which is a compound of 42·1 oxygen, 31·58 carbon, and 2·63 hydrogen. *Malic acid* is

the sour principle of apples and other fruits. It consists of the same ingredients as the former. *Tartaric acid* is the sour principle of grapes; when a large quantity of which is left to ferment, the result, it is well known, is wine. On the side of the vessel containing this liquor, crystals of the acid, combined with potash, are formed, and these, when purified, are *cream of tartar*. Twelve parts in the 100 are water; and the remaining 88 consist of oxygen 52·97, carbon 32·39, and hydrogen 2·64 parts. *Oxalic acid.*—The plant called sorrel is valued for its acidulous taste, which is conferred upon it by this acid. It has no hydrogen in its composition, consisting merely of oxygen and carbon. It is an active poison, and, from resembling Epsom salts in appearance, many persons have fallen victims to its virulence. The antidote is powdered chalk. *Gallic acid* is obtained from nut-galls. Its most remarkable property is that of changing the colour of solutions containing iron to an intense blue-black colour, as in the case of common writing-ink. One hundred grains consist of 56·25 carbon, 37·5 oxygen, and 6·25 hydrogen. *Prussic* or *Hydrocyanic acid*, found in various fruits and flowers, is a most powerful poison. It is formed of hydrogen and cyanogen, a noxious inflammable gas. Such acids as those just described exist ready formed in fruits, &c.; they are simple *educts*. But there are others formed by chemical changes produced on certain elements contained in vegetables, which afford the base of the acid; these are acid *products;* some are produced by the agency of heat, others by the action of nitric acid. *Acetic acid*, or vinegar, is one of these, being a product of any liquid capable of undergoing the vinous fermentation. Fermentation produces alcohol, and alcohol, by oxidation, is converted into acetic acid. Several acids, when distilled at a high temperature, undergo decomposition, and new acids are formed. Their names remain the same, or have the word *pyro* prefixed, as *pyrocitric acid*, *pyroligneous acid*, &c.

It has also been ascertained that *alkalies*, as well as acids, exist ready formed in plants as one of their constituent principles. Those which evince alkaline properties of a weak character are entitled *alkaloids*. The alkalies are, *quina* and *cinchona*, which resemble each other, have a bitter taste, and neutralise acids; *morphia*, which is obtained from opium, and is a white crystalline powder; *strychnia*, one of the most powerful bitters and poisons, which has of late been much used in medicine, and as a poison; *brucia*, also a violent poison; *digitalia*, which is procured from the leaves of foxglove; *hyoscyamia*, *atropia*, *veratria*, *emetina*, &c., which are derived from henbane, deadly nightshade, &c.

Of the other proximate principles, the first deserving of notice is the woody fibre which constitutes the solid basis of all vegetable structures. It is called *lignin*, from *lignum*, wood; and consists of 52 carbon, and 48 of oxygen and hydrogen, in the ratio which forms water. With lignin are associated various other bodies, such as *resins*, which are various and abundant. In the different species of the pine-tree we discover that peculiar liquid resin called *turpentine*. From resins are obtained what are called *essential oils;* because, after the resin has been heated in a distilling apparatus, an odoriferous oil distils over, and leaves the resin hard, dark, and odourless. The *essence* of the substance is supposed to have passed away in the aëriform state—hence the name. From its speedily evaporating on being exposed to the air, it is also called *volatile oil*. The seeds of plants yield another oil, which, not evaporating, is called *fixed oil*. (See CHEMISTRY APPLIED TO THE ARTS). *Gum*—for instance gum-arabic—has the following properties: namely, transparency, tastelessness, perfect solubility in water, viscidity of the solution, capability of cementing fragments, and of affording a varnish, and total insolubility in spirit of wine. There is a class of bodies called *gum resins*, whose properties are intermediate between those of gum and resin; and somewhat allied to resins, although essentially different in most of their properties, are the substances *caoutchouc* and *gutta-percha*. They are the exuded juices of peculiar trees, and are composed of carbon and hydrogen.

From wheaten flour a substance is obtained called *gluten*, from its glutinous nature. A substance called *vegetable albumen* seems to be the basis of all emulsive grains in place of starch, and greatly resembles it. *Starch* is a fine white sediment, capable of being extracted from the white and brittle parts of vegetables, particularly the tuberose roots and the seeds of the gramineous plants. One of the most remarkable properties of starch, or, as it is called, *fecula*, is that of being convertible into sugar by the action of diluted sulphuric acid. Every one, we suppose, should know what *sugar* is; being in particular a sweetener of the kindly beverages tea and coffee. It is derived from many sources—from the sugar-cane, maple-tree, beetroot, and grapes. Nothing is easier than its formation from grapes: grape-juice is to be saturated with chalk, clarified with white of eggs, or blood, and evaporated; after a few days it assumes the form of a crystalline mass. *Tannin.*—From oak-bark, or nut-galls, a peculiar substance is obtained, called tannin—so named from being the material employed in tanning leather. It is inodorous, colourless, and possesses a rough astringent bitter taste.

ANIMAL COMPOUNDS.

The chief substances which enter into the composition of animal matter are oxygen, hydrogen, nitrogen, carbon, phosphorus, and lime. We also find certain acids and metals, but in quantity so minute, as not to affect the truth of the general statement.

Bone consists principally of phosphate and carbonate of lime and *gelatine*. The latter is the coagulating, or rather elastic principle in all *animal jellies*. When bones are burned in a close vessel, they form *ivory black*. *Fibrin* is obtained from the animal tissue, and when recently obtained, it is elastic; but when perfectly dry, it is somewhat horny and transparent. The *tendons*, *ligaments*, and *membranes*, are nearly allied to gelatine in their nature. *Fatty* substances, as lard and oils, are formed chiefly of carbon, with a little hydrogen and oxygen—one or both. *Albumen* is a substance very abundant in animal matter. It occurs nearly pure in the white of eggs. Of this substance in the coagulated state, along with gelatine, are *horns*, *nails*, and *hoofs* composed.

Of the fluids of the animal body, *blood*, one of the most important, is viscid, of a red colour, exhaling a vapour of a peculiar odour. When left at rest a few hours, its appearance is very much altered, having separated into two parts—one quite liquid, of a whey-like colour, and called *serum;* the other an elastic firm jelly, of a crimson-red colour and thick consistence, resembling a deposit, which is called the *clot*. If this clot be repeatedly washed with cold water, it parts with its red colour to the water, becomes white, and a fibrous matter remains, which, when subjected to analysis, proves to be *fibrin*. Serum coagulates when heated to about 160°, nearly in the same manner as the white of an egg, but the colour is not pure white. If the serum thus coagulated be cut in slices, a fluid will exude which is called the *serosity* of blood; it consists chiefly of water, holding a little altered albumen and a little common salt in solution. Serum is composed of water, albumen, soda, and some salts of soda. Clot is composed of fibrin, albumen, red colouring matter, a little iron, and carbonic acid. During the conversion of arterial into venous blood (as explained under ANIMAL PHYSIOLOGY), nitrogen, hydrogen, and other elements are spent in the formation of new products, while the proximate principles of the blood remain, with an increased proportion of carbon. In this state it is exposed to the atmospheric air in the lungs, the oxygen of which abstracts its excess of carbon, and forms the carbonic acid expired; and this process constitutes the conversion of venous into arterial blood.

CHEMISTRY APPLIED TO THE ARTS.

CHEMISTRY, or that department of physical science which recognises the nature and composition of bodies, and the new forms and properties they may be made to assume, is now indispensable to the proper conducting of almost every useful art. Agriculture, which may be considered the most important of all the arts, is radically dependent on chemistry; for without a knowledge of that science, the husbandman remains ignorant of the constitution of his soils and crops, the action of the atmosphere and sun's light, and the properties of those materials which are required to enrich his exhausted fields. Baking, brewing, distilling, and indeed all the operations by which food is prepared from the condition in which it is furnished by nature, are in general a series of chemical processes. So, likewise, is the manufacture of pottery-ware, porcelain, glass, paper; the operations of bleaching, dyeing, and calico-printing; the preparation of soap, gunpowder, ink, salt, drugs, paints, perfumery, and various other articles in daily demand. The applications of chemistry to the arts extend to the whole circle of manufacturing industry. In the present sheet, a short account will be given of the manner in which chemistry is practically applied in the more important of those industrial operations to which we have not elsewhere alluded. The design in view is not to teach any one art, but to incite to a *general study of chemistry* among those classes who are engaged in such branches of manufacture as involve an elementary change in substances. Manufactures of this kind may be termed *chemical*, in contradistinction to those whose elaboration mainly depends upon principles that are *mechanical*. Thus, the conversion of sand, potash, and lime, into glass; of common salt into soda; iron ore into metallic iron; hides into leather; and charcoal, sulphur, and saltpetre, into gunpowder, are chiefly chemical processes: while the conversion of flax into cloth, and clay into pottery, are principally mechanical, though in both there is a necessary blending of chemical with mechanical appliances. 'Technology' being a systematic exposition of the principles upon which all processes employed in the arts are based, CHEMICAL TECHNOLOGY may be regarded as the scientific title of the present subject.

ACETIC ACID.

Acetic acid, or the sour principle in vinegar, is obtained either by the slow combustion of a liquid containing alcohol, or by the destructive distillation of wood. The former method yields the best flavoured vinegar, and is generally preferred where the acetic acid is to be used as a condiment. The alcoholic liquids employed in its manufacture are wine, beer, &c., which, when exposed to the action of the air, become sour, by the slow passage of the spirituous ingredient present in them into acetic acid. *Wine-vinegar*, as its name implies, is derived from wine, and is the most pleasant of all, as it contains, besides the real acid, some acetic ether, which imparts a pleasant *bouquet* to it; *alcohol vinegar* is manufactured from spirits; *cider vinegar* owes its origin to the juice of apples; *beer* or *malt vinegar* is prepared from the extract of grain, and is the most common variety. Pure alcohol might be kept for months and years, even exposed to atmospheric influence, and, provided evaporation were guarded against, the liquid would not change in bulk or character; but if any putrefying matter or *ferment*, and, best of all, *yeast*, be added, the alcohol passes into acetic acid. It must be noticed that this action is not fermentation, in the strict sense of the term, but is rather an instance of slow combustion. The several atoms of carbon, hydrogen, and oxygen, comprising the alcohol atom, are not simply rearranged, but a supply of oxygen is absorbed, two of the atoms of hydrogen are burned away, and two atoms of oxygen take their place.

There are two methods followed in the preparation of vinegar from alcoholic liquids: the *old* or *slow* process, which occupies some months, and the *new* or *quick* method, which requires only a few days. The former is that which is generally followed in the United Kingdom, and consists in placing stale beer, ale, or porter, or where these cannot be had, a decoction of malt, called wort (see Beer), in casks lying on their side with their bung-holes left open. The liquid fills the hogshead about two-thirds, and the remaining space is occupied by atmospheric air. After the true alcoholic fermentation has ceased (see Alcohol), the oxygen of the air is absorbed, and the combustion of the alcohol into acetic acid takes place. After some months, the change is complete; the liquid is pumped into a large store vat, where it settles; and thereafter it is clarified, by being passed through a filter composed of the stalks and skins of raisins obtained as the refuse of the British wine-manufactories.

The *quick* process depends for its rapidity on the more ready access of air to the liquid undergoing acetification. This is accomplished in a hogshead placed on its end in the ordinary way (fig. 1), and fitted up in the interior

Fig. 1.

with a grating or false bottom, about one foot higher than the real bottom. Above this false bottom are piled curled beech-shavings, soaked in vinegar, which reach near the top; whilst round the sides of the cask a number of holes are bored, so as to admit of the access of air. When the process is in operation, the liquid to be acetified is allowed to trickle slowly through openings in the top of the cask, and then falling on the shavings, is spread over a large surface, and the thinnest films of liquid thus brought into contact with the air in the interior of the cask. The result is, that the combustion of the spirituous matter into vinegar is almost, if not entirely, complete, by the time the liquid finds its way through the pile of shavings to the lower part of the barrel. The heat evolved during the chemical change assists greatly in causing a draught of air through the whole arrangement. In this manner, a volume of liquid containing one of alcohol to five of water, mixed with $\frac{1}{1000}$ of a ferment, can be readily transformed into vinegar.

A third method of procuring acetic acid is by the destructive distillation of wood. Pieces of timber are placed in an iron cylinder or retort, and heat applied. Gases and vapours are evolved, which are conducted by a pipe to a cool receiver, whilst at the same time much charcoal is left in the retort. The vapours which condense to liquids in the receiver are composed principally of pyroxylic spirit (wood-spirit) and pyroligneous acid (vinegar) accompanied by a little tar, creasote, &c. This mixture of liquids is redistilled, which vaporises the wood-spirit, and leaves the other matters in great part behind. The latter are neutralised by slaked lime, which combines with the vinegar to form acetate of lime, a salt soluble in water. On the addition of sulphate of soda to this solution, an interchange of acids takes place, and the acetic acid combining with the soda, becomes acetate of soda. The solution of the latter is evaporated to concentration, and allowed to crystallise; the crystals are separated from the impure mother-liquid, and after being dried, are calcined, to destroy any tarry matters which may still be present. The calcined mass is digested in water, which dissolves out the acetate of soda; and this solution, treated with sulphuric acid, placed in a retort, and subjected to heat, yields acetic acid or vinegar, which distils over.

The impurities liable to be present in vinegar are, sulphuric acid, lead, and copper. Sulphuric acid is allowed by law to the extent of $\frac{1}{1000}$ of the volume of the vinegar, in order to put a stop to *mothering*, or the appearance of fungus-growth in it; but in many cases it is fraudulently added, for the purpose of imparting a smarting taste to very dilute or watered vinegar. The lead and copper sometimes to be found, are doubtless derived from the pans, retorts, or reservoirs in which the vinegar is manufactured or stored; but care should be taken to exclude such metals, as they become dangerous poisons when partaken of in quantity.

ALCOHOL.

The spirituous or intoxicating principle in fermented liquors, is called by the chemist *alcohol*. The variety best known in this country is that derived from grain, in the preparation of which four distinct processes are successively followed—namely, *mashing*, *cooling*, *fermenting*, and *distilling*.

The *mashing* consists in taking a certain amount of barley, ground to a fine meal, and crushed malt (see Beer), placing them in a large tun, and covering them with water at a temperature of 150° Fahrenheit. The whole is kept agitated for some hours, during which time fresh quantities of warm water are added, and then the whole is left at rest for two or three hours for *infusion*. During these processes, the starch in the grain is in great part converted into sugar, and this dissolving in the water, forms a sweet liquid called the *wort*. The latter is drawn off from the grain, and more water added to the solid residue, which yields a larger supply of sweet wort. After several washings, the greater part of the sugar has been extracted in the wort.

The *cooling* of the wort must be quickly accomplished; and in order to effect this, the warm liquid is run into shallow wooden pans or troughs, to the depth of an inch or two, and as cool a breeze as possible, aided by cold-water pipes or fanners, soon reduces the temperature.

The *fermentation* process is that which must be most carefully watched, as a slight cause may risk the loss of the entire liquor. The process consists in the addition to the saccharine solution or wort of a minute amount of a ferment such as yeast. The latter contains a multitude of little globular bodies belonging to the vegetable kingdom (fig. 2), which always make their appearance during the putrefying of nitrogenised matter. A solution containing sugar and albumen, and to which no yeast has been added, will develop, at a temperature ranging between 64° and 77°, myriads of specimens of this yeast-plant. The distiller generally procures his yeast from the porter or ale brewer, and adds it to the wort in a large fermenting tun. No sooner do the yeast-granules meet the sugar-atoms, than a chemical decomposition commences. The sugar particles are split up partly into carbonic acid gas, which, in its escape from the tun, causes much frothing of the liquid, and in other part into alcohol, which remains behind in the liquid. (See Beer.) Notwithstanding the great commercial results attendant on this process of fermentation, yet the manner in which the yeast-plants affect the passage of the sugar into alcohol and carbonic acid, still remains a mystery. Some chemists speculate so far as to think it possible that the particles of the yeast, being themselves in a state of motion, may cause, by mere contact, motion to be communicated to the particles of sugar; whilst others consider it possible that the yeast-plant lives upon the sugar, and evolves, as the effete matters of its growth and life, carbonic acid and alcohol. Neither view accounts for the phenomenon. Notwithstanding our incapability to explain the cause, it is a fact that the sweet wort obtained in the *malting* and *cooling* processes, does undergo a change when yeast is added to it; and after some days, the greater portion of the sugar has been transformed into carbonic acid and alcohol. When such takes place, the liquor or *wash*, as it is now called, is ready for the next operation.

Fig. 2.

The *distillation* process consists in separating the alcohol from much of the water, as likewise the other substances with which it is contaminated in the *wash*. For this purpose, on the small scale, in laboratory experiments, the liquid is placed in a glass retort attached to a cooled receiver, and heat being applied, the alcohol, accompanied by a little water, passes over into the cool end of the arrangement. On the large scale, the distillation is conducted in a metal boiler with a large head terminating in a tubular beak (fig. 3). The latter is attached

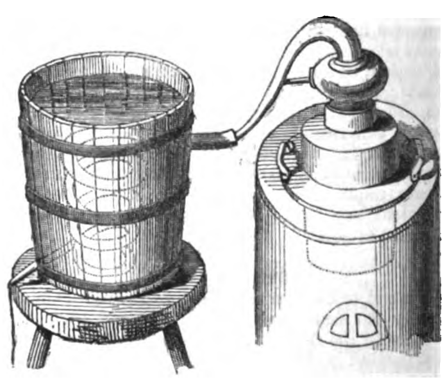

Fig. 3.

to, and communicates with, a long metal tube coiled round the interior of a barrel filled with cold water. The liquid to be distilled is placed in the boiler, a fire lit below, and the alcoholic steam rising to the head, passes into and through the coiled tube or *worm*, is there condensed, and runs from it as a cold liquid. This is the form of still used some years ago in all distilleries, as likewise in illicit distillation, but now a days very complicated and expensive apparatus is employed instead. The later improvements have been made with the view of hastening the operation; and so much is this the case, that a quantity of *wash* which, by the older stills, would have required a week for its distillation, is now worked off in a few minutes. A weak spirit—containing much water—is often obtained by the first distillation, and this is called *low wines*.

By a second distillation, the first portions which pass over are procured of a much greater strength, technically termed *doublings*.

The alcohol of commerce is always a mixture of chemically pure alcohol and water. The recognised standard is *proof*-spirit, which contains 49·50 per cent., by weight, of absolute or pure alcohol, and 57·27 per cent., by volume, with a specific gravity of 918·6. What is called *spirit of wine* or *rectified spirit* is much stronger, and has a specific gravity of 838 at 60° F. *Ardent spirits*, such as whisky, gin, rum, and brandy, are made up of alcohol, water, volatile oils, and colouring-matter, and generally contain between 40 and 50 per cent. of alcohol. Wines, such as sherry, port, claret, &c., are less strong, having only 15 to 25 per cent. of alcohol present; whilst ale, porter, and beer contain from 1 to 8 per cent.

Alcohol is used in the arts and manufactures, for the solution of resins, in the preparation of the better kind of varnishes, and as a solvent of the essential oils, &c., when it forms a numerous class of *tinctures*. Eau de Cologne is simply a tincture or solution of certain volatile oils in alcohol. As a source of heat, alcohol has long been used by the chemist in his spirit-lamps, and likewise as a solvent for many saline substances, it has proved itself useful in many ways.

The high price of alcohol in this country, and the many uses to which it might be put with great commercial advantage and profit, led the British government to introduce into our manufactures, on the 1st October 1855, a new variety of alcohol, under the name of *Methylated spirit*. This liquid is ordinary spirit of wine, to which there has been added one-ninth of its volume of wood-spirit (methylated alcohol). Such a spirit is allowed to pass into commerce duty free, and has proved itself as useful as the pure alcohol in all those arts and manufactures where such was required. The only restrictions as to its obtainment and use are such as are deemed necessary for the purpose of avoiding the methylated spirit being used as an intoxicating agent. It is not likely, however, that with the most unrestricted sale, it would ever take the place of whisky or other liqueur, as the disagreeable odour and taste of methylated alcohol renders any mixture which it may form part of, at once unpalatable. The new spirit is, however, largely employed as a solvent of varnishes and polishes, and is also employed in the manufacture of fulminating mercury, ether, and chloroform. From its antiseptic powers, the anatomist finds it of much use, as a means of preserving delicate animal membranes and other anatomical specimens.

BEER.

The raw material from which the fermented liquors in this country are prepared is barley. Pease, beans, wheat, &c., might do, but are not so readily or economically advantageous. The production of beer occupies two distinct processes—namely, *malting* and *brewing*. The latter was referred to at some length under Alcohol, but will require some further remarks here.

The passage of barley into malt is accomplished by successive steps. The *steeping* process consists in placing the barley in a large square stone box, where it is covered with water, and allowed to remain at least forty hours. Here the grain absorbs one-half its weight of water, and swells up. The superfluous water is then drained off, and the wet barley is thrown out in a heap on the floor. There it undergoes the process of *couching*, which takes place by allowing the grain to lie in the heap till it becomes warm and sweats, and ultimately the roots begin to appear. When the sprouting has proceeded some length, the plan of *flooring* is resorted to, to stop the germination. This is accomplished by spreading out the heap of grain to the depth of about six inches, and repeatedly turning it over during twelve days. The last stage of the operation is *kiln-drying*. The grain is placed on a perforated iron floor, and hot air being passed up through the openings, the barley is dried. During malting, 100 pounds of barley become eighty pounds of malt, but the deficiency is not all loss. Originally, twelve pounds of moisture are present in the grain, and this quantity deducted from the apparent loss, leaves only eight pounds of real loss during the operation. Bulk for bulk, however, the malt slightly exceeds that of the barley started with.

The chemical changes which take place during the conversion of barley into malt are considerable. Much of a woody substance called hordein is changed into starch and gum, and some starch and gum become sugar. The following table represents these changes in figures:—

	Barley.	Malt.
Hordein,	55	12
Starch,	32	56
Sugar,	5	15
Gluten,	3	1
Gum,	4	15
Resin,	1	1
	100	100

These changes proceed whilst the plumule or primary stem is advancing in growth. When the grain is kiln-dried, the roots, &c.—technically called *cummings* or *cornings*—are separated from the true body of the seed by a revolving machine. The particular kind of malt is named according to the depth of colour which it presents after heating. There are four kinds well known —*pale malt*, *amber malt*, *brown malt*, and *black malt*. The two last are somewhat charred, and are employed in the preparation of porter.

The first stage in *brewing* is the *grinding of the malt*. When reduced to coarse particles, the bruised malt is thrown into a large mash-tun, and there the process of *mashing the malt* is gone through. Water at a temperature of 160° F. is poured over the malt, and repeatedly agitated. During this stage, a substance called diastase is developed in it, which converts the remaining starch into sugar. The resulting *sweet wort* is run into the *underback*, a large reservoir, where it is graduated to the proper strength. At the same time, the insoluble matter of the malt, called draff, is carried off to feed cattle. The *boiling of the worts* takes place in a large copper, when the *hops* are added. The heating of the liquid coagulates the albuminous (white of egg) matters present—technically called *cutting the worts*—and likewise serves to extract the volatile oil, bitter resin, and tannin from the hops. The liquid is then strained, and rapidly cooled in large shallow troughs, assisted by fanners or refrigerators. After cooling, the sweet liquid is placed in the *fermenting-tuns*, the yeast added, and the fermentation process allowed to take place. (See Alcohol.) When successful, a fine light-coloured froth or head should appear, somewhat resembling *rocks*. A dark-coloured head betokens bad fermentation, and results in bad beer. The liquid, attenuated to the strength required, stands for some days to clear, and lastly is stored in barrels, where more hops are often added.

Ale for the home-market contains 5 to 7 per cent. of alcohol, and retains much sugar. That for the foreign market—such as East India pale ale—is more *attenuated* (*i. e.*, more of the sugar is converted into alcohol), and contains 10 per cent. of alcohol; whilst that forwarded to California is still stronger in alcohol, or is more *dry*. Small-beer can only boast of 1 per cent. of the intoxicating principle.

The preparation of *wine* depends on the same principles as those which regulate the production of beer. There are fewer stages, however, in the process, depending on the fact, that the material in the grape to be converted into alcohol is already sugar; whilst in the case of barley, it is mostly hordein, which must become starch, then gum, then sugar, before it is ready to undergo fermentation. In the manufacture of wine, the bruised grapes are put into a vessel, and allowed to

stand for some time, exposed to the ordinary temperature of summer. At the end of a certain period, the liquor becomes muddy; an internal motion takes place, and sometimes the temperature is found to be elevated; air-bubbles rise to the surface, occasioning a bubbling noise when they break; and the bulk of the liquid being increased, it has a tendency to boil over. From this circumstance, the process is called fermentation, from the Latin word *fervere*, to boil. The bubbles created rise to the surface, involved in a viscid matter, the whole resembling froth, which, parting with the air, subsides to the bottom, and the liquor becomes tranquil and transparent. This viscid matter is the *yeast* or *barm*. The sugar in the grape-juice has now been entirely changed into carbonic acid and alcohol, and the process is termed *vinous fermentation*.

Cider is the expressed and fermented juice of apples, and *Perry* is that of pears. Their mode of production is similar to that of wine.

BLEACHING.

Bleaching is the art by which various articles may be deprived of the colours which they naturally possess, and so rendered white. Formerly, it was the custom to submit textile fabrics in a moist condition to the free action of the atmosphere and sun's light; but this process of bleaching was tedious; and the substitution of a chemical effect, as suggested by the celebrated chemist Berthollet (1787), was a great improvement, such as the state of manufacturing industry required. Berthollet's plan consisted in employing chlorine, which possesses a wonderful power of removing vegetable colouring-matters from cotton and linen goods without injuring the fibre. The bleaching-powder, or chloride of lime, as it is usually called, is manufactured by exposing slaked lime (hydrate of lime) to the action of chlorine gas, till as much of the latter is absorbed as the lime is capable of combining with under these circumstances. The chlorine in the bleaching-powder acts upon vegetable substances by abstracting the hydrogen of the colouring-matter, and thereby compelling it to lose its hold of the cloth to which it adheres; the air would have the same effect, but would require a much longer time than can be, commercially speaking, allowed. The cloth is first singed by being quickly passed over red-hot iron cylinders, or a series of gas jets; washed repeatedly in water, alkaline lyes and soap; placed in a cold solution of the bleaching-powder for about six hours (*chemicking*), and is then taken out and washed with water. The next part of the process is called *souring*, which consists in immersing the cloth in a solution of sulphuric acid, so diluted that it does not injure the texture of the goods, whilst it improves their colour. The sulphuric acid acts on the bleaching-liquor absorbed into the fibre of the cloth, combines with the lime, and sets free the chlorine, which bleaches the cloth. The acid likewise dissolves and removes any oxide of iron with which the fabric may be contaminated, as also the lime which may have attached itself to the woven material during its treatment with the bleaching-liquor. The cloth is again washed with water, boiled in an alkaline lye, and once more carefully washed in cold water. Another solution of bleaching-powder, two-thirds the strength of the former, is then prepared, in which the cloth is immersed, and left for five or six hours, when it finally undergoes the process of souring, by which it is rendered perfectly white. The acid is carefully removed by washing. The cloth is then dried, and after each piece is stretched to its full length, it undergoes a process of mangling, by being passed successively between cylinders forced towards each other by levers, to which a considerable weight is attached. The cloth being thus stretched, smoothed, and wound upon a roller, is rendered fit for *starching*. The starch is that of wheat-flour, deprived of its gluten by remaining for twenty-four hours in water, and then passed through a sieve, which retains the bran, and allows the starch to pass. A little indigo is mixed with it, and sometimes porcelain clay. The starch is applied in the state of a pretty thick paste whilst the cloth is passing between a pair of rollers. The goods are then dried, and passed through a calender, for the purpose of giving them a gloss and texture.

Woollen and silk goods cannot be bleached by chlorine. To whiten woollen yarns and cloth, burning *sulphur* is employed. The operation is conducted in a small wooden house, in which the goods are suspended, along with a pan containing pieces of sulphur, which is set fire to by a red-hot iron being plunged into it. The doors, &c., being tightly closed, the fumes of sulphurous acid rise and fill the chamber, at the same time attacking and bleaching the wool. This operation is preceded and succeeded by numerous washings of the goods with water, alkaline lyes, and soap.

Of late years, the discoveries in scientific chemistry would lead us to anticipate that, at no distant date, the bleacher will return to a modification of the process, now antiquated, of exposing the cloth to be bleached to the action of atmospheric agents. The substance ozone (see CHEMISTRY), lately observed to be an ordinary constituent of the atmosphere, is now supposed to have been the agent which in olden times used to bleach our cloths as they lay exposed for months to wind and weather; and as ozone, when obtained in strength, has been found a most powerful bleacher, it is not too much to assert that, if it could be economically prepared, ozone would soon outrival chlorine as a bleaching agent.

CALICO-PRINTING.

The art of calico-printing consists in impressing the representation of certain figures or designs upon cloth. The mechanical part of the process consists in placing the colour on figures raised in metal or wood, and then stamping these on the cloth; or by engraving characters on a copper roller attached to a printing-machine, which fills the indentations with colour, and as the cloth passes through, allows that colour to adhere thereto. So perfect has the printing-machine now become, that a series of five or six colours can readily be fastened by the cloth passing only once through.

A piece of cloth intended for printing is first singed, bleached, and calendered. Before the application of the colour, it is often necessary to print on a *mordant*, which is generally a salt of a metal, which sinks into the cloth, and adheres firmly to the tissue. The most common mordants are salts of alumina, iron, and tin. The great use of the mordant is to absorb and retain the colour when it is printed on. Were no mordant employed, the colouring-matter would remain soluble, and the first washing the cloth received would carry much of it away; but the mordant has a great affinity for the colour, and combines with it to form an insoluble compound. Both the mordant and the colour require to be thickened, so as to give them consistence, and for that purpose gum-arabic, British gum (torrefied or heated starch), &c., are added. The proper thickening of the mordants and colours is of great importance, as it assists in stopping the running of the liquid over the cloth, and thereby gives fixity to the pattern. In impressing the representation of figures on calico goods, the object often held in view is the fixing of mordants on the cloth, which is afterwards dyed in the usual way, those parts alone which have received the mordant retaining the colour, the rest remaining white. The application, or the bringing out of the colours, is an ingenious chemical process. Madder is the substance commonly used for red by the calico-printers, and the addition of sumach, fustic, or quercitron bark, will produce a variety of tints with the various mordants at one operation. 'Suppose,' says Dr Ure, 'we wish to produce flowers or figures of any kind, containing red, purple, and black colours, we may apply the three mordants at once by the three-colour cylinder machine, putting into the first trough acetate of alumina

thickened; into the second, acetate of iron; and into the third, a mixture of the two; then drying in the air for a few days, to fix the iron, dunging, and dyeing up in a bath of madder and sumach. If we wish to procure the finest madder reds and pinks, besides the purple and black, we must apply at first only the acetate of alumina of two densities, by two cylinders; dry, dung, and dye up in a madder-bath. The mordants of iron liquor for the black, and of iron liquor, mixed with aluminous, for the purple, must be now grounded in by blocks, taking care to insert these mordants into their precise spots; the goods being then dried with airing for several days, and next dunged, are dyed up in a bath of madder and sumach. They must be afterwards cleared by branning.'

In some cases, the colour is removed from certain portions of cloth already dyed, so that they may either remain white, or receive some new colour afterwards. Sometimes a preparation is applied to cloth before it is dyed blue, in order to prevent the indigo from being fixed on those parts to which it is applied, so that they may remain white, or receive other colours. Substances possessed of this property are called resist-pastes.

After the cloth is dyed, it is washed either with soda, potash, soap, or fresh water, according to the nature of the ingredients used in the dyeing process. Great care is necessary in this department; for if the washing-liquor be too strong, the mordant may be injured. Cow-dung, diffused through hot water, is applied to calico goods at a particular stage of the manufacture. This is done in order to dissolve and carry off from the cloth a portion of the thickening matter, and also to prevent any undissolved mordant or acetic acid from injuring the blank parts of the piece. The dunging, as it is called, is performed several times, generally between the washings. The piece should be immersed, if possible, without folds; and to secure this, it is made to pass through rollers. As soon as it comes out of the dung-bath, it is washed in the dash-wheel, as in bleaching. The cloth is then finished by being passed through a calender, which greatly improves its appearance.

CANDLES.

Common tallow forms the material from which the cheaper candles are prepared. Ox-fat is first melted, which enables the fibrous and membranous parts to separate, rise to the surface, and be skimmed off, whilst the truly oleaginous matter remains liquid underneath. The skimmings are squeezed in a press, to extract any adhering fat, and the residue is sold as *greaves* or *cracklings*, to feed dogs, &c. The melted fat is poured into moulds, and stored till required by the candlemaker. Tallow-candles are known as *dips* or *moulds*, according to the particular process they pass through. The apparatus required in the preparation of dips is an upright post supporting a wheel with eight to twelve horizontal arms like spokes, at the further end of each of which dangles a light framework, with 100 to 150 cotton-wicks suspended thereto. The operation commences by bringing one of the spokes, with its host of wicks, right over a trough containing melted tallow, and ducking the wicks therein for a minute or so, when they are withdrawn, and resume their station mid air. The wheel is then moved round a peg, and a second spoke with wicks attached is brought above the trough with melted tallow, and the ducking, &c., takes place again. Then the third and fourth spokes have their turn in the tallow-bath; and this process goes on round and round the wheel till all the wicks attached to the spokes present the required thickness of combustible matter. By such an arrangement as has been described, one man will suspend, dip, and prepare 1500 candles an hour, which gives the work of one day as no less than 15,000 dips. *Moulds* are of a firmer texture than the *dip*-candle, and are prepared from a mixture of ox-tallow and mutton suet. In their manufacture, a pewter mould, the same shape as the candle, is employed, which has a wick suspended in the centre, and into which the melted mixture of tallow and suet is poured. These common varieties of tallow-candle—namely, the dip and the mould—have now been, to a very great extent, superseded by those prepared by a more modern process, which yields candles of such excellence that they rival the best wax. This process is one which involves a certain amount of knowledge regarding the chemistry of the more common fatty substances, which we now proceed to give.

Some years ago, M. Chevreul, a French chemist, undertook an investigation into the nature of fatty substances, which he found to be composed of what we now know them to be—two materials, *stearine* and *oleine*. He ascertained that the oil does not combine directly with an alkali, but that its two components are decomposed by it into two corresponding acids, the stearic and oleic, and a basic body called *glycerine*, with which both are naturally in combination.

M. Chevreul separated these acids from their compounds, and found them possessed of the following properties:—Oleic acid is a liquid, clear when pure, and closely resembling oil; stearic acid is solid, and resembles wax in so striking a manner as to be with difficulty distinguished from it. If the reader wishes to prepare and examine the artificial wax himself, it may be easily accomplished. Let him dissolve a little hard white soap in hot rain or distilled water, and to the clear solution, while hot, add some vinegar or other acid. The stearic, being a weak acid, is easily separated from its combination with soda, as it exists in soap. Acetate of soda is formed, which remains in solution, and the stearic acid rises to the top of the liquid as an oily substance, which, on cooling, solidifies into a cake of artificial wax, mixed with a certain portion of oleic acid and impurities, which render it softer than if this fluid had been expelled by pressure. A similar process is pursued on a large scale, but regard must be had to economy. The tallow is saponified, not by soda or potash, as in the preparation of soap, but by quicklime. It is only necessary to boil the lime, tallow, and water in a large vessel for some hours, when these ingredients are converted into a kind of hard soap. From this substance—namely, the stearate and oleate of lime—the stearic and oleic acids are separated by the addition of oil of vitriol. The acids are afterwards melted like tallow, run into cakes, and subjected to the powerful action of a hydraulic-press; this separates all impurities, and leaves the stearic acid as pure and white as the finest bleached wax, which may be used immediately for the formation of candles. In France, the wicks, besides being plaited, are dipped in a solution of borax, and then dried. The borax fuses during the combustion, and forming a globule on the summit of the wick, assists by its weight to bring it out of the flame in contact with the atmosphere, and thus insures perfect combustion, and obviates the necessity of snuffing. Palmer, an English patentee, accomplishes the same end by making the wick consist of two halves, which are twisted in opposite directions, and at the same time wrapped round a rod or wire, which is withdrawn when the candle is made. The result is, that the halves separate on combustion, and fork outwards to the exterior portion of the flame, where they are completely consumed.

It was found that the artificial wax generally crystallised in the moulds—a circumstance which prevented the formation of a solid candle. In England, this difficulty was overcome in some cases by the addition of arsenic; but the use of this substance either for this purpose, or for causing the wicks to be more readily reduced to ash, ought never to be permitted, as it is highly prejudicial to health. The French, more scientific than we, had recourse to their knowledge of the laws of crystallisation for the remedy. It is known that regular crystallisation only takes place when the transition

of the mass from a fluid to a solid state is so gradual, as to allow time for its molecules to arrange themselves in those determinate forms called crystals: this condition was fulfilled in the cooling of the moulds and their contents; but by plunging them in cold water as soon as the melted stearic acid had been poured in, crystallisation was prevented, and a perfectly solid candle procured. Stearic candles, which can with difficulty be distinguished from wax-candles, are now manufactured on a large scale in England, and, from their comparative cheapness, are coming universally into use in the houses of the middle and higher classes of society.

More recently, palm-oil has been introduced and used with great success as a source of material for candles. This oil consists of palmitine (composed of palmitic acid and glycerine, and resembling stearine) and oleine. As brought to this country, it is a soft solid of the consistence of butter, and of an orange-yellow colour. In order to bleach the oil, it is thrown on hot water, when it readily fuses; it is then either simply exposed to the sun's light and the presence of air, when it becomes white in about fifteen hours; or, whilst in a state of fusion, it is acted upon by bichromate of potash and sulphuric acid (or hydrochloric acid), which evolve nascent oxygen, and the oil is bleached in five minutes or so. After being washed, the purified oil is saponified by lime, as before detailed, and sulphuric acid is thereafter added, to separate the oleic and palmitic acids. The latter is a fine white solid, and is now most extensively employed in the manufacture of imitation wax-candles. Coco-nut oil, bees-wax, and an African vegetable wax, are also employed. Mixtures of the several oils and waxes are often desirable. Equal parts of stearine and coco-nut oil, with a little bee and African wax, make *composite candles;* whilst a mixture of spermaceti and stearine gives the *opaline sperm-candles*, much liked, and generally used on board sea-going steamers.

Glycerine.—In connection with the manufacture of candles, we have to allude to the substance which is separated from the oils in the preparation of the stearic and palmitic acid. By the ordinary process of saponifying the oil with lime along with water, the glycerine was separated in the water in an impure state, and it was only by a tedious operation that the pure material was arrived at. In 1855, however, a new process was suggested, and has been carried out on the large scale, in which lime is dispensed with, and the oil is decomposed, and its glycerine separated by means of heat and steam alone. The palm-oil is introduced into a capacious distilling apparatus, and steam at a temperature of 550° to 600° Fahrenheit forced through the oil. The components of the oil, principally palmitic acid and glycerine, are separated from each other, severally combine with water, and then distil over, mechanically mixed, as the palmitate of water and the hydrate of glycerine. The former, being the lighter of the two, swims on the surface of the mixed fluids, whilst the glycerine remains dissolved in the great bulk of water (condensed steam) underneath. When first distilled, the solution is weak, and requires to be concentrated; and if at all discoloured, can be purified by redistillation. It is then obtained of the specific gravity of 1240, and contains 94 per cent. of anhydrous glycerine. The purposes to which glycerine may be applied are numerous. It possesses a great power of preserving animal matter from decay. Fish, when newly caught and immersed in glycerine, not only remain fresh to taste and smell, but likewise retain the colour of their scales as perfect as when they were sporting in their native element. Anatomical specimens can likewise be preserved in all their integrity. It is useful in skin diseases, as also in chapped hands and sunburnt faces. In some instances it can be advantageously substituted for sugar or sirup in the maintaining of medicines in their active state, and in the preservation of fruits, of which it is supposed by many to improve the taste. As an agent in photography, glycerine seems likely to occupy a high place; and as a material to inject into the bladder for the purpose of dissolving calculous deposits, it has been deemed worthy of trial.

CHLOROFORM.

This important substance is prepared from four parts of bleaching-powder, one part alcohol, and twelve parts of water. The bleaching-powder and water are first intimately mixed together, introduced into a capacious distilling apparatus, thereafter the alcohol added, and heat applied. A liquid distils over, which is in greater part water, accompanied by a little alcohol; but underneath the stratum of water will be observed globules of an oily-looking substance. This is the chloroform, which is purified by washing with water, and redistillation from a retort containing chloride of calcium. The cheap methylated spirit may be employed in this process; and the large quantities of chloroform now prepared from the cheaper spirit, cannot be distinguished from that manufactured from pure grain alcohol. Chloroform is a very volatile liquid, with a density a little less than 1500, and is slightly combustible, burning with a greenish flame. It is sparingly soluble in water, and should not be coloured by cold sulphuric acid. When sparingly given to an animal, it brings on a period of excitement; but when administered in comparatively large doses, it produces insensibility to pain, so that the most severe surgical operations can be performed whilst the patient is enjoying unbroken slumber. (See MEDICINE AND SURGERY.)

COLOURS—PIGMENTS.

There are, as is well known, two modes of imparting colours—dyeing and painting; the former term being applied to articles coloured by a liquid infusion, and the latter to the laying of a colouring substance on the surface. We *dye* cloth, and *paint* a house. The materials employed in dyeing are usually drugs, salts of some kind, or vegetable fluids; but in painting, the prepared colours are chiefly pigments. The preparation of dye-stuffs and pigments is one of the chief departments of practical chemistry.

The substances used as *paints* are partly artificial, and partly natural productions. They are derived chiefly from minerals by certain chemical processes; and even when animal or vegetable substances are used for colouring, they are always united with a mineral substance (an earth or an oxide), because by themselves they have no body, which they acquire only by a mixture with a mineral. In painting, the colours are ground to a great degree of fineness, and applied, by means of some liquid, with a brush or camel-hair pencil. Different fluids are employed for this purpose; and the difference of the material used, with the method of employing it, has given rise to the modes of painting in water-colours, oil-colours, in distemper, and in fresco (painting on damp plaster as an absorbent). Oil-paints are usually prepared with boiled linseed-oil, which is drying in its nature; the colours employed all consist of metallic oxides, or salts, or of combinations of sulphur. Among the metallic oxides used as pigments are minium and massicot, from lead; the ochres, burnt sienna, umber, from iron; smalt, from cobalt. Among the salts, or saline metallic combinations, are white-lead, kremnitz white, from lead; Prussian blue, from iron; verdigris, mineral green, Brunswick green, from copper. Metallic combinations containing sulphur are cinnabar, from quicksilver, and orpiment, from arsenic. The lake colours have tin or alum for their bases, and owe their tint to animal or vegetable colouring substances. Among these are the red or pinkish lakes prepared from cochineal, madder, and Brazil-wood; the yellow, from fustic, &c.; the brown, from several other colouring barks; finally, indigo, which, however, is entirely vegetable. In

staining porcelain and glass, the metallic colours which are not driven off by heat, and are not easily changeable, are used. Gold containing tin gives a purple; nickel, green; cobalt, blue; iron and manganese, black; uranium, yellow; chrome, green. From the chromate of iron, or rather ferruginous oxide of chrome, one of the most beautiful yellow pigments is now prepared for the use of painters. Ultramarine, another of our most beautiful, and, till lately, one of the most expensive of our pigments, was originally obtained from the lapis-lazuli, a mineral of unrivalled azure blue, and composed of silica, alumina, and soda, three colourless bodies, with sulphur, and a trace of iron. It is now prepared artificially by combining those substances in their proper proportions.

The material principally employed by respectable house-painters to give consistency to their paints, is white-lead or ceruse. This substance is an oxide of lead saturated with carbonic acid. It is prepared by exposing thin plates of lead in a closed vessel to the vapours arising from hot vinegar. The vapours of the acetic acid become saturated with the metal, and change the latter into a whitish substance, which is scraped from time to time off the plates. The whitish substance is afterwards pulverised, and mixed with properly prepared oil. Much of the white-lead in common use is adulterated with whiting—that is, purified and ground chalk—which is much less durable, and may be easily washed off by an alkaline solution.

More recently white-lead has been extensively adulterated with ground heavy spar, or sulphate of baryta. This substance occurs largely in cracks or fissures in rocks, especially in the island of Arran, and is readily purified from the oxide of iron with which it is coloured, by being ground to powder, and digested in dilute sulphuric acid. When purified, it yields a fine white powder, which, so far as regards weight, rivals ordinary white-lead; but as it does not form a body with linseed-oil, its presence in the white-lead of commerce is always injurious. This form of adulteration is carried on to a very large extent, and even the coloured paints suffer, as the ground heavy-spar is likewise manufactured as a yellow powder, by the addition of a little chromate of lead, as a blue compound from admixture with Prussian blue, and as a green pigment by the addition of both chromate of lead and Prussian blue. So much is this adulteration carried on at the present day, that no less than three mixtures of white-lead with sulphate of baryta are regularly prepared for, and sold in the market. *Venice white* contains equal parts of white-lead and sulphate of baryta; *Hamburg white* is a mixture of one part white-lead and two parts of the baryta compound; and *Dutch white* is composed of one part white-lead, and no less than three of the comparatively useless sulphate of baryta. Pure white-lead is known in commerce as *krems* or *kremnitz white*, *silver white*, and the *clichy white*. A little indigo or lampblack is often added, to impart a blue tint to the white-lead.

Oil or spirit of turpentine is also largely used by house-painters, who style it *turps*, chiefly for the purpose of imparting a drying quality, or of deadening the glitter of the paint. Turpentine is a fluid extract from certain kinds of fir-trees, from which it exudes, and being distilled, the oil or spirit of turpentine is obtained; the residuum is resin. Turpentine is of a powerful acrid quality, and is now employed for certain purposes in medicine. All the *varnishes* used by painters are of the class of gums or resins, properly prepared—such as copal, mastic, sandarac, lac, gum-lac, dragons' blood, &c. All are extremely inflammable, and great caution is necessary both in their preparation and general use.

Inks, either for writing or printing, are as much the result of chemical operations as paints or dyes. *Black ink* is a decoction of partly vegetable and partly metallic substances, the basis of the latter being iron. The ingredients commonly used are Aleppo galls in powder, logwood, gum-arabic, and sulphate of iron, in certain proportions; but latterly the art of manufacturing the article has been greatly improved, chiefly with the view of giving great fluidity as well as colour. *Blue ink* is either sulphate of indigo and tanno-gallate of iron; or, what is better, Prussian blue is dissolved in a solution of oxalic acid. *Red ink* is made by boiling two ounces of Brazil-wood in a pint of water, and adding some gum and alum. A better sort is manufactured from carmine, one of the colouring principles in cochineal, by the addition to it of ammonia.

Marking-ink, so universally used for marking linen, is a solution of nitrate of silver in water. The cloth is first damped with a solution of iodide of potassium, or even potash itself, allowed to dry, and the nitrate of silver solution written on. The silver is reduced, and appears black where such has taken place. The popular notion that this ink is indelible, or cannot be bleached, is far from the truth, as by the use of cyanide of potassium, the ink gets loosened from the cloth, and may be dissolved and washed out. A more certain and lasting marking-ink is that employed by bleachers to mark the cloth they receive from various manufacturers. This consists of a solution of tar in coal naphtha.

Printing-ink is quite a different substance from either of those mentioned, being a thick viscid body, resembling a black paint. Its ingredients are boiled linseed or nut-oil and lampblack, in the proportion of two and a half ounces of black to sixteen ounces of oil. The preparation of the oil is one of the most dangerous processes in the arts, and great care is required to prevent conflagration of the oleaginous material. There are various qualities of ink to suit different kinds of work. The prime object of attainment in making printing-ink, is to give it a deep black colour, which will endure after exposure on the pages of a book. Unless very great trouble be taken in grinding and mingling the materials in exact proportions, the ink, on being used, will gradually become brown, by the spreading of the oil. The French printing-inks are much superior to those made in Britain. *Indian ink* is used in China for writing with a brush, and for painting upon the soft flexible paper of Chinese manufacture. It is ascertained, as well from experiment as from information, that the cakes of this ink are made of lampblack and size, or animal glue, with the addition of perfumes, or other substances not essential to its quality as an ink. The fine soot from the flame of a lamp or candle, received by holding a plate over it, mixed with clean size from shreds of parchment or glove-leather not dyed, will make an ink equal to that imported. A variety of what are called *sympathetic* inks have been invented which might withstand all chemical obliterants. Some of these are made to remain invisible till some re-agent be applied, others require chemically prepared papers, and others, again, can be rendered visible or invisible at pleasure.

DYEING.

A remarkable circumstance connected with dyeing is the different degrees of facility with which animal and vegetable substances imbibe the colouring-matters applied to them. Tissues composed of the former, as silk and wool, receive more brilliant colours than those composed of the latter—as cotton and linen. The cause of this difference has not hitherto been discovered.

Although, in the most numerous class of cases, it is easy to impart colour to various tissues, yet when these become exposed to moisture, the dye-stuff is removed. It has therefore been found necessary to employ certain chemical substances which shall have the property of permanently fixing the colour upon the body which is dyed. These substances have obtained the name of *mordants* (from the Latin word *mordere*, to bite), because they were supposed at first, figuratively speaking, to bite the dye into the cloth. The same name has also been applied to those preparations which possess the property of altering the shade, or of heightening the colour, as it

is called. The latter, at the suggestion of Berthollet, are sometimes termed *alterants*. The action of the mordants in fixing the colour on the cloth is very decided. If a piece of calico be simply soaked with a solution of the colouring-matter of Brazil-wood, and thereafter washed, the whole of the dye can be washed out; but if the calico be first immersed in a solution of acetate of alumina (a mordant), and thereafter treated with Brazil-wood solution, it acquires a permanent red colour, which cannot be washed out. The principal mordants are—alumina employed in the form of a salt, as that of the acetate of alumina, and of alum; the oxides of tin, employed like the former in the shape of salts, which are prepared by dissolving tin in muriatic acid. Silk and woollen dyers, however, employ nitric acid or aqua-fortis for forming the salts of tin which they use. The salts of lead and copper are likewise had recourse to as mordants; and the gall-nut, which contains two very peculiar vegetable substances—tannin and gallic acid—is not only employed as a mordant, but also as a simple and powerful dye-stuff.

By varying the mordant, a great variety of shades may be derived from the same colouring-matter. Indeed, the mordant itself, in many instances, supplies a colour. For example, in dyeing with cochineal, when the aluminous mordant is employed, the colour produced is crimson; but when oxide of iron is substituted for the alumina, a black colour is the result. Cloth first treated with a mordant of acetate of alumina, and thereafter with a decoction of madder, Brazil and peach woods, comes up a *red;* with the same mordant and cochineal, a *pink;* with the same mordant and madder alone, a *lilac;* with the same mordant and quercitron and Persian berries, a *yellow.* With a very dilute solution of acetate of iron as a mordant, cloth becomes a *red* with madder; with stronger solution, a *purple* is produced; and a still stronger gives a *black. Chocolates* are procured by treating the cloth first with a mixture of the iron and alumina mordants, and thereafter dyeing with madder. *Yellows* are formed by immersing the cloth in solution of acetate of lead, and afterwards in solution of bichromate of potash. *Oranges* are readily produced by taking the cloth already dyed yellow, and boiling it in dilute milk of lime, or even washing-soda. *Browns* are formed by heating the cloth in solution of the sulphate of manganese, and passing it through caustic soda, and lastly placing it in solution of bleaching-powder.

When parts of the cloth are to remain uncoloured, it is necessary to print on a substance which destroys or throws off the colour. The *dischargers* in common use are not many. *Citric acid* is employed, mixed with gum, for the purpose of dissolving the alumina and iron mordants, and thereby unfitting those parts it is printed on from receiving a fixed or fast colour. *Tartaric acid* being printed on cloth, and the fabric then passed through solution of bleaching-powder, the acid sets free chlorine, which bleaches white the parts it adheres to. *Oxalic acid* discharges the iron mordant. *Protochloride of tin* discharges sesquioxide of manganese, and leaves a white instead of the brown. If the tin solution be previously mixed with Brazil-wood or cochineal, the brown of the manganese disappears, and a *pink* is left instead; mixed with logwood, the tin solution leaves a *purple*, and with Prussian blue, a *blue*. The yellows produced by acetate of lead and bichromate of potash are likewise discharged by protochloride of tin. The *protochloride of iron* sets free the manganese brown, and leaves an iron buff instead.

ETHER.

Ether is very closely connected with alcohol. Both contain a compound substance called ethyle—a compound of four equivalents of carbon, and five of hydrogen. Ether is built up of ethyle and one atom of oxygen, and is therefore the oxide of ethyle. Alcohol, on the other hand, is compounded of ethyle, an atom of oxygen, and an atom of water; and, strictly speaking, is the hydrate of the oxide of ethyle. Alcohol, therefore, differs from ether in containing an atom of water, which the latter has not; and, for practical purposes, the alcohol may be best regarded as made up of ether and water in a state of chemical combination. The substances employed in the preparation of ether are alcohol and sulphuric acid. The apparatus required is a capacious flask or retort attached to a good condenser (fig. 4). Two volumes of

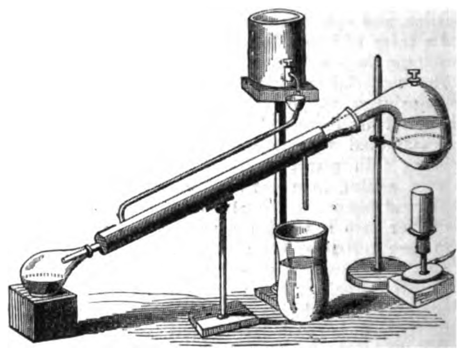

Fig. 4.

alcohol are first placed in the flask, and one volume of sulphuric acid is by degrees poured into the alcohol. The mixture must be well agitated, and thereafter heat applied. The chemical reaction which ensues is very complicated; but the result is, that the sulphuric acid so acts as to disunite the atom of water from the ether, which admits of both the ether and the water distilling over together in a condition of *mere mechanical mixture.* What comes away from the distilling apparatus is in one sense the same matter that was mixed with the sulphuric acid and introduced at first into the vessel to be heated; but now the chemical force which previously clasped that matter together has been overpowered, or otherwise directed by the sulphuric acid, and in consequence, the materials, ether and water, distil over, *mechanically mingled*, but not *chemically combined.* By the first distillation, the ether comes over contaminated with much water, and a little sulphurous and acetic acids. It is agitated with potash or lime till the upper layer of liquid, containing most of the ether, is not acid, which is then separated from the lower layer, and redistilled.

Ether is a colourless and transparent liquid, very mobile, with a very decided and characteristic taste and odour. Commercial specimens have a specific gravity at 60° F. of 740. Heated to 96° F., it boils, but it may be subjected to the most severe cold without freezing. Placed on the hand, it evaporates very rapidly, and leaves a sensation of cold. At ordinary temperatures, it readily evaporates from an open vessel, and forms a vapour with the great density of 2586, being 2½ times the density of common air. It is soluble in water to the extent of one volume in ten of water. It mixes with alcohol in all proportions; but on the addition of water, the alcohol is withdrawn, and the ether remains floating above. It is very inflammable, and burns with a yellow white flame. Mixed with air or with oxygen, and a light brought near, ether forms a most explosive compound. This property necessitates the employment of very perfect apparatus in the preparation of ether on the large scale, and, to avoid the chance of accidents, it is customary to have the opening to the fire on the outside of the building—the still in one room, and the receiver in another. Ether is useful as a solvent of fats and oils, as likewise of phosphorus. To the photographer it is of importance, as it furnishes

him with a liquid, which, in conjunction with alcohol, affords a ready means of dissolving gun-cotton and yielding collodion, so remarkable for the rapidity and accuracy with which it admits of sun-portraits being taken. Prior to the introduction of chloroform, ether was employed as an anæsthetic agent, but has been discontinued as such in so far as human subjects are concerned. It required a much larger quantity than chloroform, was not so expeditious in producing sleep, and left the patient more exhausted, and a prey to sickness, headache, and other after effects. Moreover, the combustibility and explosibility of ether rendered it much more dangerous to handle than chloroform.

GUM AND GUM-RESINS.

At one time the term *gum* was given to all exudations of plants, but now it is limited to a few, and from these all the gum-resins are excluded. The best example of a true gum is gum-arabic, which is exuded from a species of acacia growing in Arabia, India, Upper Egypt, and Senegal. The gum itself is of a white or yellow-white colour, and occurs in irregular masses with a conchoidal fracture. It is soluble in cold water, and in boiling water dissolves to the extent of 19 parts in every 100 of water. It is not soluble in alcohol or in ether. Gum is used in many processes: it is largely employed as a thickener of mordants and colours in dyeing, and of the various inks used for writing and printing. It is also used as a glaze or varnish, and to confer a gloss and stiffness to ribbons, linen, cotton, &c. When ground, it is often adulterated with starch, which may be detected by the production of a blue colour, when iodide of potassium and chlorine water are added.

British gum, *dextrine*, or *torrefied starch*, are terms applied to a gummy substance artificially prepared by heating ordinary starch. It is less expensive than true gum, and for the majority of purposes can be employed with advantage in its place. Unlike ordinary starch, it is quite soluble in cold water.

Gum tragacanth, or *gum-dragon*, is obtained from a species of astragalus growing in Asia Minor, Armenia, and Northern Persia. It differs from gum-arabic in not being completely soluble in water. The more modern views held on this subject represent it as composed of 50 per cent. arabine, 30 per cent. tragacanthine or bassorine, and 20 per cent. water and oxalate of lime. When bassorine is placed in cold water, it swells up into a kind of mucilage, but when boiled, it becomes entirely soluble. *Gum cerasine*, obtained from the cherry, plum, and almond trees, is identical with bassorine. In commerce, gum tragacanth occurs in white or yellow-white semi-transparent flakes, curled up, with much the appearance of horn.

Gum-resins are secretions from trees in warm climates. Many exude spontaneously, but an incision in the bark always expedites the process. When they pass from the tree, they are generally light-coloured liquids, but they soon solidify into a dark-coloured hard substance. They are composed partly of gum and partly of resin; hence they dissolve in part in water, and in part in absolute alcohol. A mixture of water and alcohol, as in *proof-spirit*, dissolves the gum-resins when heated over them: some gum-resins are popularly but erroneously named *balsams*, as they contain no benzoic acid.

GUNPOWDER AND GUN-COTTON.

The discovery of *gunpowder* rests in obscurity. The Chinese seem to have employed a coarse variety, about 200 years B.C. for fireworks, but not as a propelling agent. From China this impure gunpowder found its way to the Arabs, and they in their turn communicated the discovery to the Greeks. It is possible that gunpowder may have formed the principal ingredient in the *Greek fire*. The impure materials out of which the earlier specimens were manufactured only admitted of the comparatively slow combustion of the mixed mass; and it was not till the fourteenth century, when the ingredients were employed pure, that a gunpowder fit for being used as a projectile agent was manufactured.

The substances employed in the manufacture of gunpowder are nitre, charcoal, and sulphur. The exact proportions in which these ingredients are mixed differ according to the country, as also the use to which the powder is to be put; nevertheless, there is a great similarity between the various kinds of gunpowder, as will be noticed by comparing the figures in the following table, which gives the scale of proportion in 100 parts, adopted in different national and private gunpowder-works:

	Nitre.	Charcoal.	Sulphur.
Royal mills at Waltham Abbey,	75	15	10
French, for war,	75	12·5	12·5

Switzerland,	76	14	10
China,	75·7	14·4	9·9

Saltpetre, nitre, or nitrate of potass, is abundant in nature, but may be also compounded by the artificial union of its two ingredients—nitric acid and potass. During the seventeenth century, before the importation of nitre from the East Indies commenced, the nitre required for gunpowder was procured by washing (lixiviating) the soil forming the floors of stables, pigeon-houses, and other outhouses. Special acts of parliament were granted to certain *saltpetre men*, whose business consisted in travelling through the country, and every now and again digging up clay-floors, putting the earthy matter in large tubs with water, agitating the mixture well, and thereafter boiling down the liquid, when a liquid nitre was obtained. Now-a-days, however, we derive our supply of that substance from the East Indies, where it is found on the surface of limestones, marls, and chalky strata, as likewise in the soil, being spontaneously generated there by electrical storms, and by the natural decay and putrefaction of vegetable and animal matter containing nitrogen. The slight silky tufts of the nitre are swept up with a broom, and are lixiviated, allowed to settle, evaporated, and crystallised. In this state it is exported; but the impurities which it contains require its subjection to successive solutions and crystallisations, ere it can be employed in the manufacture of gunpowder. The last process is that of fusion in iron pots at a regulated heat. It is tested by adding to its solution in distilled water nitrate of silver, with which it ought to occasion no perceptible milkiness.

Charcoal, as is mentioned in CHEMISTRY, is simply wood reduced to a charred condition (pure carbon), by being burnt to a kind of blackened cinder in a vessel closed from the atmosphere. For making gunpowder, light woods, such as the willow and alder, are the best, the pieces being stripped of their bark before being used. In preparing this kind of charcoal, it is important that the vapours be allowed freely to escape, otherwise the combustibility of the charcoal will be impaired. The preparation is usually effected in iron retorts over furnaces; and by a connecting-tube the vapour escapes, and is condensed into a tarry liquid, from which pyroligneous acid (acetic acid) and wood-spirit are afterwards extracted. When thus prepared, the charcoal is reduced to a fine powder.

Sulphur is procured in many volcanic countries, but the great emporium for it is Sicily. It can also be obtained from the metallic sulphurets, as from iron pyrites. At the gunpowder works it is purified for use

either by distillation or by fusion. In the first instance, the pure part is distilled over; and in the second, skimmed off, the impurities being left behind.

The three ingredients, charcoal, nitre, and sulphur, being duly prepared by trituration, and passed through fine sieves, are mixed and carried to a mill, where they are properly blended, by the pressure of a revolving stone on edge. The stone is of a calcareous quality, and goes round on a bedstone of the same nature. No metal or sandstone is employed either about the machinery or the mill-house, in order to avoid the danger of sparks. On this bedstone the composition is spread, and moistened with as small a quantity of water as will, in conjunction with the weight of the revolving stones, bring it into a proper body of *cake*, but not of *paste*. The line of contact of the edgestone is preceded by a scraper, which goes round with the wheel, continually scraping up the cake, and turning it into the track of the stone.

The proportions in which the ingredients are mingled are usually 77½ parts of nitre, 16 parts of charcoal, and 10½ parts of sulphur. This mixture is introduced into the bed of the mill in charges of forty-two pounds' weight, moistened with about two pounds of water. In summer, more water is required than in winter. After being three and a half hours in the mill, the *mill-cake*—as the gunpowder is now called—is taken out, and layers of it are placed between sheets of copper, and subjected to a pressure of seventy-five tons on every superficial foot, which serves to force the particles nearer each other, and gives a firmer and more compact mass. This is broken into small pieces by passing through two teethed rollers, or by being struck with wooden mallets; after which the graining is executed by placing these lumps in sieves, on each of which is laid a disk of lignum-vitæ. The sieves are made of perforated parchment or hair-cloth. Several such sieves are fixed in a frame, which, by proper machinery, has such a motion given to it as to make the lignum-vitæ runner in each sieve move round with considerable velocity, so as to break the lumps of the cake, and force the substance through the sieves, forming grains of several sizes. These granular particles are afterwards separated from the finer dust by proper sieves and reels. The corned powder is next hardened, and the rougher edges taken off, by being revolved in a close reel or cask turning rapidly on its axis. This vessel somewhat resembles a barrel-churn: it should be only half full at each operation, and has frequently square bars inside, parallel to its axis, to aid the polish by attrition. This glazing operation is often effected in a skeleton barrel lined with canvas in the interior, and revolved rapidly. Only the better varieties of gunpowder put on a gloss by simple attrition. The inferior varieties have such communicated to them by placing some black-lead in the barrel along with the grains of gunpowder. The result is, that the face of each gunpowder particle is rubbed bright on the same principle as housemaids rub the faces of their grates bright. The gunpowder is now dried, which is done generally by a steam-heat, or by transmitting a body of air, slightly heated in another chamber, over canvas shelves covered with the damp gunpowder.

The combustibility of gunpowder is too well known to require particular mention. When burned, it almost entirely becomes gas, one volume of gunpowder expanding to 787¼ volumes of cold air or gas; but as the vapours are much heated and expanded when they leave a rifle or a piece of ordnance, it is nearer the truth to say that one volume of gunpowder fired in a gun tends to expand to 2000 times its own bulk. It is the sudden creation of such a volume of gas that renders gunpowder of so much use in projecting bullets, balls, and shells, and in rending rocks and minerals in our mining operations. The enormous force of gunpowder may be noticed from the following experiments:—Count Rumford placed in a war-mortar one-twentieth of an ounce of gunpowder, and placed on the mouth of the mortar a cannon (24-pounder) weighing 8081 pounds. When the gunpowder was fired, the mortar was burst, and the weighty cannon was lifted up. Again, twenty-eight grains of gunpowder were enclosed in a cylindrical space, which they just filled, and when fired, the gas formed tore asunder a piece of iron which would have resisted a strain of 400,000 pounds.

White gunpowder is the name given to an explosive compound introduced two or three years ago, and intended to be a likely substitute for black gunpowder. It is prepared by carefully drying and pulverising in *separate* vessels two parts chlorate of potash, one part ferrocyanide of potassium (yellow prussiate of potash), and one part white sugar. When in a state of fine division, the three ingredients are to be cautiously mixed on a wooden platter with a wooden spatula, and immediately thereafter stored for after use. Great care must be taken not to resort to friction of any kind after the materials have been mixed. This precaution is necessary to avoid unlooked-for explosions. The white gunpowder is more explosive than gunpowder, and produces, when burned, amongst a host of other gases, a little hydrocyanic (prussic) acid gas. This property would render its employment dangerous to those in charge of a gun in a man-of-war or an ill-ventilated land-battery; and this fact, coupled with its being composed of more expensive materials than common gunpowder, has hindered its ever being employed on the large scale, even on trial. It may be noticed in passing, that the white gunpowder, besides being readily fired by a flame or red-hot iron, is likewise inflamed by a drop of concentrated sulphuric acid. This latter method of firing a similar compound was resorted to by the Russians in the infernal machines which they anchored so numerously in the Baltic Sea during the recent war. The concussion of a vessel coming against the machine was to have caused the acid enclosed within to spill on the explosive substance.

Gun-cotton.—Much interest and excitement was some years ago caused by the announcement of a substitute for gunpowder, which was said to be four times more powerful than that substance, weight for weight; to ignite at a much lower temperature; to be uninjured by water; and to burn without smell, smoke, or residue. This substance was the gun-cotton of Dr Schönbein, to whom the credit is due of discovering and making known the various useful purposes to which this remarkable body may be applied, although its actual discovery dates from a period prior to that when Schönbein published his experiments. Without entering upon either its history or its theoretical composition, as manifested in what are called xyloidine and pyroxyline, we shall merely advert to the plan adopted for the preparation of gun-cotton in the laboratory of the chemist—no minute description of its manufacture upon a commercial scale having yet been published. Well-cleansed cotton is immersed for several minutes in a mixture composed of equal parts* of the most concentrated nitric and sulphuric acids. The acid should then be pressed out, and the cotton, which remains impregnated with it, be well washed with water, until no acid reaction is perceptible to the tongue; it is now dried at a temperature below 212° Fahrenheit. Care should be taken in drying this substance to allow a free current of air to pass over it, and to spread out the cotton as much as possible, to prevent its forming into dense masses, which are said to be much more liable to explode. The temperature at which gun-cotton explodes is very various. At times, a specimen will resist, without exploding, a heat of nearly 400° Fahrenheit, whilst other samples explode much below 212°, the boiling-point of water. This difference in the exploding temperature led to the destruction of large works which were constructed in England for the manufacture of gun-cotton. Depending

* Schönbein recommends the use of three parts sulphuric acid, and one nitric acid of the specific gravity 1·5.

on the material not exploding at a water-bath heat, the drying-room was fitted up with hot-water pipes, but one of the first days on which the operations were proceeding, the gun-cotton in the drying-room exploded, and blew the manufactory to pieces.

When pressed in the hand, gun-cotton has a crepitating sound and feel, exactly resembling that heard and felt when one is kneading a snow-ball, at the time the snow is in the best condition for that purpose. On the continent, the gun-cotton is always dyed a particular purple tint, so as to lessen the chances of its being mistaken for ordinary cotton. It is very inflammable; so much so, that a little placed on the hand and set fire to, burns away so quickly that it does not hurt the hand. It is insoluble in water, hot and cold, and when plunged in water, removed, and dried, is found to have lost none of its original properties. It explodes violently when heated, or on ignition, leaving scarcely any residue, and creating very little smoke. The temperature at which it is thus decomposed is so much below that at which gunpowder explodes, that the cotton may be lightly placed upon the surface of gunpowder, and detonised by a red-hot wire without setting fire to the powder. Friction of the ordinary kind will not explode gun-cotton; but when placed on an anvil, and powerfully struck with a hammer, the heat generated by the stroke causes it to detonate. With reference to the projectile force of gun-cotton as compared with gunpowder, no authoritative statements have yet been made; but there appears reason to apprehend that its action in its present form is too rapid, and resembles too much that of fulminates, to render it applicable to the purposes of artillery. The gaseous products from its combustion are also such as cannot be altogether resisted by firearms, although, if air be absent, no great amount of corrosion can ensue; and as it has been found that gun-cotton impregnated with chlorate of potash or nitre has a still more powerful effect than that prepared in the usual way, the addition of these substances would at the same time tend to modify the corrosive action of the acid products of combustion. As a substitute for gunpowder in all mining and blasting operations, however, the superior local force of the cotton will be highly valuable; and it has indeed been found to effect as much as four times its weight of powder. Gun-cotton, like gunpowder, contains everything within itself requisite to its complete combustion; indeed, in the elementary composition of both, there is little or no difference.

The advantages which gun-cotton possesses over gunpowder are—1. One-fourth of the weight of material produces an equal effect, and hence a great saving in the carriage, in case the gun-cotton ever came to be largely used; 2. It burns completely away, and leaves no residue; hence there would be nothing left in the firearm to interfere with correct aim; 3. When it becomes wet or moist, it can be dried again, and is as good as ever; and 4. No smoke results from its combustion. Its disadvantages are—1. The great bulk that cotton, from its lightness, naturally assumes, which would render it necessary for a sportsman or soldier to carry a considerable-sized bundle instead of a small cartridge-box; 2. In its combustion much steam is developed, which would moisten the gun; 3. It explodes at such a low temperature that a gun repeatedly fired would quickly become so hot that the gun-cotton would take fire whenever it was rammed home;* 4. The production of nitrous acid fumes, which would tend to corrode the metal of the gun; and 5. Its price, which would be about four times that of ordinary gunpowder.

Loose cotton is not the only form in which woody fibre can be rendered explosive by the action of acids; the latter can resolve muslin cloth into *gun-muslin*, linen into *gun-linen*, tow into *gun-tow*, sawdust into *gun-sawdust*, and paper into *gun-paper*—all of which are more or less explosive.

The importance of gunpowder as an agent in blasting rocks cannot be overlooked. An ounce or two of powder, ingeniously directed, will detach more rock in an instant of time than a dozen of men will accomplish in a week. The general plan of operation is to bore a narrow hole two or three feet into the rock, pour in an inch or two of gunpowder, and plug the opening firmly, with the exception of a small canal or passage. This is filled with gunpowder, and the shot thereby fired. Vast quantities of building-stone, road-metal, coal, &c., are now dislodged by this force. Considerable danger undoubtedly attends the present system of firing the shots by the ordinary fuse; but if managers of such works could be brought to see fully the advantages of firing the charges by galvanic electricity, in place of the fuse, all danger would be avoided, and the employment of gunpowder as a blasting agent be rendered at once safe and practicable.

LEATHER.

Leather-making is the art by which the skins of animals are rendered impervious to the action of those external agents which would otherwise decompose them. This effect is brought about by steeping the skins in the astringent principle called *tannin* or *tannic acid*, when a chemical combination of the skin and tannin ensues, which is leather. This operation may be performed either with the hair on, or, as is generally the case, when it is taken off. Tannin is obtained from the bark of a number of trees, particularly the East India catechu, the common oak, the Spanish chestnut, the Leicester willow, &c. It is found in the largest quantities in catechu—one pound of this being equal to seven or eight pounds of oak-bark. Tannin is also obtained by a peculiar preparation from the gall-nuts of the Levant oak. When the bark of trees is to be used for tanning, it should be stripped from the trunk and branches in the spring, when the sap flows most freely. The trees should not be less than thirty years old, for it has been found that the bark possesses more tannin when old than when in a young state. The bark, when dried, is ground in a mill, to reduce it to a rough powder, after which it is ready to be used.

The first process which the skins undergo is steeping in lime and water of three or four different strengths, which is continued for a longer or shorter time, according as the skins are dry or fresh. Sometimes the skins are salted when they are imported from abroad; and in this case they require to be steeped in water, beaten, and rubbed, until they are brought to a fresh state. The hides are moved about or *handled* in the lime-and-water vats; and in the course of three weeks or so, the hair-sheath is decomposed, and the lime combines with the fat to form an insoluble soap. The horns are then cut off, and the skins put in heaps for a day or two, after which they are hung up in a shed. During this process, the slight putrefaction which takes place enables the hair on the one side, and the fleshy matter on the other, to be easily removed. This is done by a blunt knife, or scraper, the skins being stretched upon a wooden beam called the *horse*. The skins are then immersed for about forty-eight hours in water mixed with a little sulphuric acid, which has the effect of distending the fibres, causing the skins to swell. This process is called *raising*, and by it the tannin principle more easily reaches the inner fibres. When sufficiently raised, the skins are put into a pit with a layer of bark in the bottom. On this skins are laid, and then bark and skins alternately. The pit is filled up with a strong decoction of bark, and the whole is allowed to lie undisturbed for about six weeks. At the end of this time, it will be found that the tannin has become entirely exhausted; when the skins must be

* This is not mere speculation, as, at the siege of Mooltan, gun-cotton was tried, and whilst its propelling force was everything that could be desired, yet the gun soon got so warm as to render it advisable to cease firing.

taken out, and put again into the pit, along with fresh bark. In this they are allowed to lie for three months; and the process is repeated two or three times, according to the quality of the leather required. From six to eight months in all are sufficient to complete the tanning of the commonest kind of sole-leather, called *crop* by the trade; but for the better kinds of sole-leather, from a year to a year and a half will be required. *Bend-leather* is the strongest of all sole-leather, and in manufacturing it, the tanning process is continued for a longer period than is necessary for crop. The best and thickest skins also are selected for this kind. When properly tanned, crop-leather is hung up in an airy house to dry, which is performed slowly, and the article is then fit for the market. Bend-leather, after being dried, is beaten into a firm consistence, so that when cut, the edges present a glossy appearance. The instrument with which bend-leather is beaten is a broad brass hammer; and this kind of leather may be easily distinguished from its being darker in the colour, in consequence of lying longer in the tannin. A coarse kind of upper leather is also made from cow-hides, the weakest and thinnest being selected for this purpose. The skins of seals, calves, &c., are manufactured into upper leather.

Several improvements have recently been made in the manufacture of leather, by which the tannin principle is more readily admitted to the inner fibres of the skins. One of the improved methods consists in using a machine of two rollers, which is placed in the middle between two tan-pits. The hides having been previously divested of the hair, &c., are fastened together, and put into the tan-pit in regular folds. After lying in this for a certain time, the end of the belt of hides is laid upon the under roller, which, being set in motion, carries the belt over to the other tan-pit. This is done without pressure; but when the hides have become soft, the upper roller is pressed down against the under one. The hides are again passed through between the rollers, which press out the exhausted tannin, and prepare them for being submitted to a fresh infusion. More recent improvements are those of Mr John Cox of Gorgie Mills, near Edinburgh, for which he has obtained patents. His great object is to force the liquid tannin into the vesicles of the skin, which is sewed into the form of a bag, and immersed in tanning liquor, while the interior is also filled and compressed from a supply of liquor through a pipe from a cistern placed a few feet above the pit. Dr Turnbull of London has likewise patented a very ingenious process, depending upon the principles of *endosmose* and *exosmose;* and another, in which the forcing-pump is employed to expedite the impregnation of the hide with the tanning liquid. The theory of endosmose and exosmose teaches us that when two fluids of unequal density are separated by a membrane, the heavier fluid will attract the lighter through that membrane. Upon this principle, the skins are sewed up in the form of bags filled with a super-saturated solution of tannin, and placed in a reservoir filled with a sub-saturated solution—or *vice versâ*—upon which the permeation goes on with rapidity.

Skins intended for the *manufacture of gloves* require in the first place to be washed with pure water, and immediately after being washed, the skins must be worked, or they are liable to become marked with indelible spots. They are now rubbed upon a convex beam, and the rough parts removed with the fleshing-knife. The fleshy sides of the skins are covered with a cream of lime, and piled together with the wool sides of each pair outermost. They are left in this state for from four to six days, or until the wool is found to come easily off. The skins are then washed in a running water, to free them from the lime, and the wool is taken off by means of small spring tweezers. After this, they are fleeced smooth by a rolling-pin, or by rubbing with a whetstone.

The next operation is steeping the skins in a strong solution of lime, for the purpose of swelling and softening them. They are now put into weak lime-water, and drained upon inclined tables, which is repeated several times, the process occupying about three weeks. The outsides are then rubbed with a whetstone, to remove any wool which may still remain; after which, the skins are fit for what is called *branning.* Into twenty gallons of water, forty pounds of bran are put, and the skins are steeped in this mixture until they sink, which they will generally do in about two days in summer, and eight in winter. During the branning process, the skins must be frequently stirred, that each may get a due share of the liquid. They are next steeped in a solution of alum and sea-salt, which is called the *white stuff.* From twelve to eighteen pounds of alum, and about three pounds of salt, are put into a copper with twelve gallons of water. This mixture is dissolved by heating the copper; and when about to boil, three gallons of the solution are poured into a basin, in which twenty-six skins are worked one after another. The twelve gallons are thought sufficient for one hundred skins; and when all have been worked, they are allowed to steep for about ten minutes. The skins are then taken out, and fifteen pounds of wheat-flour are added to the solution. This is next run out of the copper vessel, and the yolks of fifty eggs put into it, in which the skins are worked, and afterwards allowed to steep for a day. They are then taken out, stretched upon poles, and allowed to dry. By this operation, the leather is rendered very white and soft, which enables it to bear the working of the softening-iron. This consists of a plate of iron about a foot broad, mounted upon an upright beam thirty inches high, which is fixed to the end of a plank three and a half feet long. This plank is heavily loaded; and the skins having been previously wetted, are rubbed with the iron upon a board. The skins are sometimes stretched upon the horse, and well rubbed with a blunt two-edged knife, and afterwards polished with pumice-stone. They are then worked upon the stretching-iron, and afterwards smoothed with a hot iron. Sheep-skins are frequently dressed for household purposes, and on this account are technically called *housings.* For this purpose, those skins are selected which have the longest and most beautiful fleece.

Chamois leather is prepared by washing, steeping in lime-water, taking off the fleece, and then branning the skins as before described. The outer skin, or epidermis, is next cut off upon the horse, which removes all excrescences, and renders the skins equal in thickness. They are then branned for a short time, and well beat in a fulling-mill. The skins are afterwards oiled; subjected to a fermenting process; washed in potash lye, and dried. The very thick and firm, but pliable sort of leather, called *buff* (originally made from the hide of the urus, or wild bull of the forests of Poland, Hungary, and Russia, but now also from cow-hides), is dressed in oil, and prepared much in the same way as chamois.

Morocco or *Turkey leather* is manufactured from goat-skin, but a spurious article is frequently sold under this name, which is made from sheep-skin. The process is much the same as for glove-leather, except that the washing is performed oftener, and the skins are salted previous to being dyed. Morocco leather is dyed with cochineal, about an ounce being required for each skin. The cochineal gives a scarlet colour to morocco leather; but other colours may be given to it, such as black, by using the red acetate of iron; blue, by indigo; yellow, from the roots of the barberry. The skin is next tanned in a decoction of sumach. The tanning is performed twice, the process requiring about twenty-four hours. The skins are then rubbed hard with a copper blade, and hung up to dry.

Russia leather, well known for its durable properties, is prepared by steeping in alkaline lye, and then in

dogs' dung; after which it is fulled and tanned with birch-bark. It is generally dyed of a pale-orange colour, is roughened in the surface by an iron tool, and receives its peculiar odour from being rubbed with the empyreumatic oil of birch. *Maroquin*, commonly of a red or yellow colour, is another Russian leather similarly prepared. *Shagreen*, brought chiefly from Astrakhan, is prepared from the strong skin which covers the crupper of the horse or ass. Its peculiar granulated surface is produced by treading small round seeds into the skin when soft; these are afterwards removed, the leather dyed green, and the surface worked down by rasping, when it finally presents the appearance of white dots on a green ground.

Currying is the process by which the newly tanned rough leather is converted into the soft, flexible, and jet-coloured article from which the upper leathers of shoes are made. The currier first steeps the leather, and placing it upon a piece of basket-work, beats it with a mallet, in order to soften it. By means of scraping and paring with knives of a variety of shapes and degrees of sharpness, the inequalities of the surface are now removed, and the uniformity of the texture improved. The leather is then pommelled by an instrument grooved on the under side, and with a cross strap on the top, under which the hand of the workman goes. The leather is folded with its grain side in contact, and rubbed strongly with the pommel, which gives it a granular appearance and greater flexibility. It is then conveyed to the drying-house, where grease is applied to soften it. The grease employed is a mixture of tallow and cod-oil, called *dubbing*, and is applied to the leather by means of hard brushes upon a large broad table. When well greased, the leather is hung up to dry, in order that it may thoroughly imbibe the oily matter; and afterwards it is well scraped, to free it from all superfluous oil, which would otherwise injure its appearance, and prevent it from receiving the colour readily. The leather is now rubbed on the flesh side with a brush dipped in a composition of oil and lamp-black, until it is thoroughly black. It is then black-sized with a brush or sponge, rubbed again with the oily matter, and afterwards scraped with glass. When coloured (that is, blacked) upon the grain side, a solution of sulphate of iron or copperas is employed. The leather is then wetted with stale urine, and afterwards rubbed with an iron, to render the grain as fine as possible. The bright shining varnish now common on dress-boots is called *enamelling*.

Cow-hides, when dressed for upper leather, are called *neat's* leather, and the shoes made from it are coarse. Common shoes are in general made from calf-skin, which is prepared in the same manner. The uppers of boots are all made from calf-skin, the best part for this purpose being the back and flank. This also applies to cow-skin leather. A considerable number of shoes are made from a description of leather called *kip*, which is prepared from the hides of young cattle, and is consequently intermediate in quality between calf-skin and cow-hide. Horses' hides were formerly much used for making leather, generally known as *cordovan;* but they are now almost entirely superseded by cow-hides, which are greatly preferred.

Parchment is prepared chiefly from the skins of sheep and she-goats. The skins are steeped in the lime-pit, deprived of their wool, and stretched tightly on a wooden frame, where they are repeatedly scraped and ground with fine lime and pumice-stone, and then allowed to dry, still in the state of tension. After drying, they undergo a second set of manipulations, in order still further to equalise the thickness and smooth them. *Vellum* is a finer kind of parchment, made from the skins of calves, kids, and young lambs. Pigs' skins are prepared in this way for covering church-books. For drum-heads, sieves, battledores, &c., skins of goats, calves, wolves, asses, &c., are used.

NAPHTHA.

In many parts of the world, but especially in Trinidad, a vast quantity of a black substance, *asphaltum*, is found. In general, it is a thick, viscid, and even hard mass; but occasionally soft and even liquid portions are observed, which owe their fluidity to the presence of *naphtha* and *petroleum*. The great source, however, of naphtha is the destructive distillation of coal. In the coal-gas works, there are evolved from the retorts, besides the gas itself, certain vapours, which become liquid as they pass through the *coolers* or *condensers*, and these consist of *naphtha*, *tar*, *ammonia*, and *water*. When this mixture is allowed to settle, the ammonia and water sink to the lower part of the lake or vessel, and the tar dissolved in the naphtha, floats above. The upper liquid being drawn off, and introduced into a retort, is distilled, and the first portions which come over are composed essentially of naphtha. The variety of coal which yields naphtha in largest quantity is the famous Boghead coal, which can be so distilled in a retort as to evolve little or no gas, but pass off entirely as naphtha and true oil. (See Oils.)

When rectified, naphtha has a specific gravity of 750 to 820. It burns readily with a smoky flame, and possesses great illuminating powers. It is accordingly employed as a source of light; and when the lamp is so constructed that the liquid is heated, and the vapour is driven out to be consumed, it produces perhaps the most brilliant and dazzling light in common use. It is not soluble in water, but readily mixes and dissolves in absolute alcohol, ether, and the essential and fixed oils. It boils at a temperature ranging between 320° and 365°. It is extensively used in the preparation of the cheaper varnishes, as also for dissolving caoutchouc in the manufacture of water-proof cloth.

Naphthaline is a substance somewhat resembling naphtha, and obtained as a solid crystalline matter, during the distillation of naphtha from coal-tar. It fuses at 176°, and boils at 413°. In its combustibility and solubility, it much resembles ordinary naphtha.

OILS AND FATS.

There are two distinct classes of oils—namely, the *essential* or *volatile* oils, and the *fixed* or *non-volatile*. As these differ widely in their properties, it will be better to consider them separately.

1. Essential or Volatile Oils.

These are the odorous principles of plants, which in some instances, as in those of the orange and lemon peel, can be squeezed out. When placed on paper, they evaporate, and do not leave a greasy stain. The best examples of the class are turpentine and camphor. *Turpentine* is obtained from trees of the fir-tribe, and its collection is carried on to a large extent in America. The bark of the tree is cut in spring, when the juices are in active motion, and a thick treacly mass exudes, which is common turpentine. When this is placed along with water in a still, and heated, the water begins to boil, and the steam rising up through the upper stratum of common turpentine, carries away the volatile principle contained therein, and leaves behind the fixed matter, which is common resin. The product of distillation, collected in a cooled receiver, consists of two layers of liquid, the upper one of ordinary spirits of turpentine, and the lower one water. The upper stratum can be siphoned off, and constitutes the turpentine of commerce. When the exudation from the cut surface of the tree is allowed to dry on the tree, and thereafter purified by fusion, it hardens into *Burgundy pitch* or *cobblers' wax*. Rectified turpentine is a clear liquid, with a hot taste and peculiar odour. It is insoluble in water, and is very inflammable, burning with a sooty flame. It is much used in the manufacture of varnishes, and the many kinds of furniture-polish, as also by the

painter in oil-colours, who, under the name of *turps*, mixes it with the oil-paint, in order to hasten the drying.

Camphor is obtained from the *camphor laurel*, a plant growing in China and Japan. The wood of the roots, stem, and branches, is chopped up into fragments, and thrown into a boiler containing cold water. The head of the boiler is made of earth, and contains straw. When the water is heated, the steam carries off the camphor, which is deposited in coarse particles, like raw sugar, on the straw. These impure grains are placed in a glass flask, nearly spherical, with a small opening at the upper part. Heat is cautiously applied; the last traces of water accompanying the crystals are allowed to escape, when the opening is closed, and the camphor vapour slowly sublimes from the lower part of the flask, and accumulates in the upper cool half. When the operation is finished, the flask is broken, and the cake of purified camphor taken out. Camphor is a white, semi-transparent solid, with a fragrant odour, an index of its volatility. It is very inflammable, and is so light that it floats in water, and may even then be set fire to. It is not soluble in water, but is readily dissolved by alcohol, &c.

The other odoriferous and volatile oils agree in their mode of manufacture with that pursued in the preparation of turpentine and camphor.

Oil of cinnamon is procured from cinnamon, the bark of the cinnamon-tree growing in Ceylon; *oil of cloves*, from cloves, the unopened flowers of the clove-tree, found in the Moluccas; *oil of lavender*, from the common lavender plant, extensively grown in Surrey in England; *oil of nutmegs*, from nutmegs, the fruit of the nutmeg-tree, cultivated in the Moluccas, Sumatra, Java, &c.; *oil of peppermint*, from the dried peppermint plant common in Britain; and the oils of *bergamot*, *aniseed*, *caraway*, *cassia*, *chamomile*, *copaiva*, *dill*, *juniper*, *lemon-peel*, *marjoram*, *orange-peel*, *penny-royal*, *rosemary*, *rue*, *sassafras*, and *spearmint*, from the respective plants, or portions of plants, which contain them.

2. Fixed or Non-volatile Oils.

This division includes those oils which have no power of volatilising at a water-bath heat, and which leave a fixed greasy stain on paper, when they fall on such. They may be liquid or solid; the property of fluidity or solidity being the result of the mere application of heat or cold, does not chemically alter the constitution of the particular oil. Palm-oil in this country is solid, having the consistence of butter; but in Africa it is liquid. Olive-oil is liquid here, but in the arctic regions it is a solid; and the same remark applies to tallow, hog's lard, coco-nut oil, &c. The same property is observable in water, which may be liquid in temperate regions, solid at the poles, and gaseous in our kettles or steam-boilers, but is still the same substance, water.

Olive-oil is obtained from the fruit of the olive-tree, which is cultivated extensively in Italy, and to a less extent in Syria, Palestine, Greece, &c. The fruit is bruised and subjected to great pressure. The oil at once flows away, and the finer varieties are sent into the market as *virgin salad oil*. Much of the oil remains with the vegetable albumen of the fruit, and cannot be extracted by pressure. It comes away, however, when hot water is added, and the pressure renewed. The oil which is thus obtained is known as *Gallipoli oil* and *Florence oil*, and is not such a fine pure oil as that obtained by pressure alone.

Coco-nut oil is manufactured from the kernel of the nut of the coco-nut tree, which grows wild near the coast of all tropical countries, especially in Brazil. The operation consists in detaching the husk from the nut, which is then broken, and after drying, is exposed to compression, or ground in a mill. In tropical regions, the oil is liquid, but in this country, excepting a few days in summer, it is solid. This oil is used in lamps in Ceylon, and many natives anoint their bodies with it. It is much used in this country in the preparation of soap, and even of candles, and forms a good substitute for olive-oil in the formation of ointments, plasters, &c. When heated, and resin added, a material is produced which does well for filling in the seams of ships, and for preserving corks of bottles from the ravages of insects.

Palm-oil is obtained from the oil-palm growing on the western coast of Africa, south of Fernando Po. The fruit of this palm is about the size and shape of a pigeon's egg, and has a yellow colour. On being bruised into a pasty consistence, and treated with hot water, the oil rises and floats on the surface of the water, where it congeals as it cools. As brought to this country, the oil has a more or less yellow colour, a sweet taste, and a pleasant odour. It melts between 80° and 100°. It is principally composed of a white solid substance called *palmitine*, which is itself compounded of palmitic acid and glycerine. Palm-oil is most extensively employed in the preparation of composite candles. It can readily be bleached white by exposure to air, or by the action of bichromate of potash and sulphuric acid.

Almond-oil, *castor-oil*, *linseed-oil*, *poppy-oil*, &c., are manufactured in an analogous manner from the seeds or fruits of the plants in which they are naturally contained.

Animal oils require little notice. *Butter* is the oil peculiar to the milk of the mammalia. *Tallow* is a generic title, comprehending the fat of many animals, including the ox and the sheep. *Mutton suet* is restricted to the fat of sheep, and *beef suet* to the fat of oxen. *Lard* is the fat of the pig.

With few exceptions, the oils, vegetable and animal, are composed of *oleine*, *margarine*, and *stearine;* and these respectively contain *oleic*, *margaric*, and *stearic acids*, in chemical combination with a sweet principle named *glycerine*.

The uses to which oil may be put are multitudinous. Some of these have been referred to, others remain to be noticed. As a lighting agent, *train-oil* and *sperm-oil*, both from the whale tribe, are employed. *Sweet-oil*, procured from rape-seeds, supplies a good lubricating agent. *Cod-liver oil*, extracted from the liver of the cod-fish, affords a valuable medicinal agent. *Olive-oil* is much prized for culinary purposes. *Linseed-oil*, when boiled, is largely used in the manufacture of oil-paints; whilst all the oils and fats, without exception, form more or less useful soaps, when boiled with water and an alkali.

Recently, a new source of oil has been discovered. The Boghead coal, when distilled at a comparatively low temperature, yields much liquid matter and little gas. The liquid can be separated into (1) an oil, valuable as a lubricating agent; (2) an oil, rivalling sperm-oil in readiness and brilliancy of combustion, and in affording a smokeless and odourless source of light; (3) a solid substance, called paraffine, capable of being manufactured into first-class candles; and (4) a naphtha of the finest quality, much prized for illuminating purposes, and for dissolving resins to make varnishes.

SOAP.

This exceedingly useful article, of which the ancients were entirely ignorant, is a compound of certain ingredients in oils, fats, or resin, with a salifiable base. If this base be potash or soda, the compound is used as a detergent in washing clothes. When an alkaline earth or oxide of a common metal, such as lead, whose oxide is litharge, &c., is the base, the compound is insoluble in water. The insoluble compounds, however, are very little used, except in some few cases of medical treatment. Animal fat, grease, or tallow, as it is variously termed, is a compound of a solid substance called, in chemistry, *stearine*, and of an oil called *oleine*, the basis of which is carbon, with a little hydrogen and oxygen. On subjecting tallow to a hot lye of soda (or potash), a

chemical change takes place in the constituents, and we have the material named *margaric acid*, and a fluid, *oleic acid*, and together they enter into a saline combination with the alkali. The result, a soapy substance, is thus said to be a union of margarate of soda and oleate of soda. Saponification also takes place with vegetable fats and oils, which are now largely employed in commerce.

Common *hard white soap* is made chiefly from soda and tallow. The soda was at one time extracted from kelp, which was made by reducing certain kinds of sea-weed to ashes by burning; the result in soluble material is a crude alkali, consisting mainly of carbonate, sulphate, and muriate of soda and potash. It was manufactured in large quantities on the shores of the Western Isles of Scotland and Ireland; but has latterly been disused, in consequence of the substitution of barilla, and especially of soda-ash from the decomposition of sea-salt. This branch of manufacture—the conversion of common salt into common soda—is now carried on to a very large extent. The solution of soda is now generally prepared by dissolving common soda in water, and adding thereto slaked lime—the supernatant liquid is diluted with water to the required strength, and constitutes the lyes used in the soap-manufacture. A quantity of lye, not well defined, but known by experience, is poured on the melted tallow, and the mixture is boiled, a workman agitating the materials to facilitate the combination. The fire being withdrawn, and the aqueous liquid having subsided, it is pumped off, and a new portion is thrown in. A second boil is given; and so on in succession. Two or three boils are performed every twelve hours, for six days—constituting twelve or eighteen operations in the whole. Towards the last, the stronger lye is brought into play. Whenever the workman perceives the saponification perfect, the process is stopped, and the matters are allowed to settle. The impurities are deposited in the pan, which, from their colour, are called *niger*, and the scum is taken off. After standing some days, the soap is lifted out, poured into the moulds, and afterwards cut into bars.

Though tallow is the principal oil employed in the manufacture of *white soap*, yet, when the price will admit of it, lard is added to the extent of 50 per cent. or more, which gives the soap a fine 'smooth skin.' Coco-nut oil is also added occasionally to the extent of 10 per cent.

Yellow or *resin* soap is prepared in a similar manner as that detailed above—from tallow, resin, and soda. For this kind of soap, beef-tallow is generally employed, as the yellow tint which it possesses renders it not so useful for preparing white soap, for which the purer and whiter mutton-tallow is retained. In the manufacture of yellow soap 100 parts of tallow are mixed with 20 parts resin, the alkaline lye added, and heat applied. After repeated boilings with fresh lye, other 20 parts of resin are added, and the boilings again resumed. After six days, the mixture is allowed to settle, the *niger* separates, and the soap is put into frames, and cut into bars as usual.

Mottled, *marled*, or *speckled* soap, which is now a favourite in the north of Scotland, is resin soap which has not been permitted to deposit its *niger*, and therefore still retains its impurities, which are the cause of its peculiar appearance.

The compounds of tallow or oils with potash (derived from the ashes of land-plants) remain of a soft consistency, and form what are termed *soft soaps*, useful in scouring. We can only afford space for an account of the process of manufacturing one of the common kinds of soft soap, as lately practised by an eminent soap-boiler near Glasgow. Whale or cod oil, to the amount of 273 gallons, is put into a boiler, along with four hundredweights of tallow, and 252 gallons of potash lye. On heat being applied, the mixture froths up very much, but means are adopted to prevent its boiling over. There are then added at intervals fourteen measures of stronger lye, each measure holding twenty-one gallons. After suitable boiling without agitation, the soap is formed, amounting in all to one hundred firkins of sixty-four pounds each from the above quantity of materials. The manufacturer is not particular as to the oil employed in this soap. Any refuse olive, linseed, or other oils, as well as the *niger* of the better soaps, are thrown into the pan. The peculiar spotted appearance which the *soft economical* or *black soap* presents, is formed in it after standing some weeks. The *figging*, as it is called, is supposed to be a spurious form of crystallisation.

Toilet soaps are either made from common white soap, or from purified hog's lard, with the addition of olive, almond, palm, coco-nut, and other oils. These, when prepared, are perfumed with various scents. The soap is cut into thin shavings with a plane, and melted in a pan placed within a hot water or steam bath. When melted, the colouring-matter and perfume are added, which generally consist of vermilion for bright red, *ochre* for dull red, *saffron* for light yellow, *Prussian blue* for blue, and *Spanish brown* for brown, such as that of Windsor soap; accompanied by the scent, which may be the *essence of bergamot*, *musk*, *orange-blossom*, *cinnamon*, *&c.*

Castile soap, or *Spanish* soap, is prepared from olive-oil and alkaline lye.

Certain soaps contain admixtures of certain detergent mineral substances, as silica, alumina, soap-stone, porcelain-earth, and fuller's-earth. The firmness of the soap is not diminished by the addition of such substances, which exert, however, a purely mechanical action, and are contained in no kind of chemical combination. The value of the article so manufactured is very much reduced, as a great portion of the real soap is replaced by a substance of similar, but inferior efficacy, and whose price bears no comparison with that of the fats. *Sand soap*, for example, is one of those recent manufactures, and contains from 60 to 70 per cent. of pure sand; *pumice soap* is another, containing from 20 to 30 per cent. of silicious matter; and *silica soap*, perhaps the best of them, about 20 per cent. of insoluble residue. *Chlorine soaps* are preparations intended to realise the idea of the union of the detergent properties of soap with the bleaching effects of the compounds of chlorine. It is almost unnecessary to remark that such a union is impracticable; and these chlorine soaps, in the words of a high authority, 'are nothing more than foolish novelties.'

PYROTECHNY.

The class of combustibles in the manufacture of which a knowledge of chemistry is more particularly required, includes gunpowder, gun-cotton, fulminating powders, the material of Congreve and sky rockets, bomb-shells, percussion-caps, rapidly igniting matches, and of fireworks generally. The term *pyrotechny* (from *pyr*, fire, and *technê*, art) has been applied to the art of making and compounding these substances.

The leading ingredients in most explosive combustibles are charcoal, saltpetre or nitre, and sulphur. In making fireworks of a varied kind, however, numerous other substances are employed. The chief are chlorate of potass, fulminating silver, and mercury, preparations of steel, copper, and other metals, with various oils, spirits, and resins.

Rockets.—The common modern rockets, which are generally employed as signals or tokens of rejoicing, may be described as tubular cartridges of paper, pasteboard, wood, or metal, filled with combustible substances, which, on ignition, cause the cartridge to shoot rapidly through the air. The principle on which rockets rise in the air is simple, and may be explained here, once for all, as it applies to all varieties of flying fireworks. A vessel containing a fluid which tends to expand, will be motionless so long as the vessel

is closed on all sides, because the pressure is then equal everywhere; but if an opening is made, the pressure will not be equal, and the vessel will then tend to move towards the side on which the whole pressure still remains. If the opening be below, the tendency will be to rise; and if the expansive force be great enough, and the vessel sufficiently light, the vessel will obey the pressure and ascend. When the expansive force is exhausted, it will again descend, by the ordinary influence of gravitation. In the case of the rocket, the combustion commencing below, creates the expansive gas, and the pressure forces the rocket upwards. The rocket moves upwards from the same cause that makes a musket move backwards when fired; only that the recoil of the rocket is continuous, because the explosion is continuous. The cartridge or tube, commonly of pasteboard or pasted paper, must be very strongly formed, if large, and intended to ascend high. The charge of sky-rockets varies according to the bore of the cartridge. Nitre 16, sulphur 4, and charcoal 7, are the contents and proportions of the charge when the bore is three-fourths of an inch; and the charcoal is merely increased a very little when the bore is enlarged. The composition is such that it does not explode all at once, but consumes gradually. This is the common rocket, with the usual light of gunpowder. When a rocket with a *brilliant* light is wanted, three parts of fine steel-filings are added; and when the light called *Chinese-fire* is desired, three parts of fine borings of cast iron form the addition to the three ingredients first mentioned.

The *garniture* of a rocket, as the crackers, showers of fire, stars, serpents, &c., are called which are commonly attached to it, with what is termed the *pot*, are of course added before igniting the charge in the central tube or fusee. 'The pot is a pasteboard tube, wider than the body of the rocket, and one-third of its length. After being strangled at the bottom like the mouth of a phial, it is attached to the end of the fusee by means of twine and paste: these are afterwards covered with paper. The garniture is introduced by the neck, and a paper plug is laid over it. The whole—for still greater strengthening—is enclosed within a tube of pasteboard terminating in a cone, which is firmly pasted to the pot. The quick-match is now finally inserted into the *fusee* or *soul* of the rocket, and a light rod or stick attached to the end of the whole, to keep it in a perpendicular ascent.' The beauty of the rocket depends much on the style of the garniture. These, whether stars or serpents, are charged fusees, stronger or weaker, formed into the shape wanted, and giving kinds of light modified by the ingredients. Stars which give golden showers are formed of nitre, 10; sulphur, 10; charcoal, 4; gunpowder, 16; lampblack, 2. *Petards* are sealed cartridges, which burst in the air; and *crackers* are square boxes of pasteboard, hooped and charged with gunpowder. But the finest accompaniment of the rocket is the Roman candle, which is a fusee so formed as to throw out in succession, as the combustion reaches them, very fine stars. These stars are small cylindrical masses of nitre, sulphur, and gunpowder, steeped in spirits and gum.

Congreve rockets, first used in the attack of Boulogne, 1806, are of various dimensions, and are differently armed as they are intended for the field or for bombardment. Those of the first sort carry shells or case-shot; the others are armed with a very combustible material, and are called *carcass rockets*. Their form is cylindrical, and they are composed of strong metallic cases. The sticks employed for regulating their flight are of different lengths, according to the size of the rocket. The carcass rockets are armed with strong iron conical heads, pierced with holes, and containing a substance as hard and solid as iron itself, which, when once inflamed, is inextinguishable, and scatters its burning particles in every direction. When this substance is consumed, the ball explodes like a grenade. The rocket is projected horizontally, and whizzes loudly as it flies through the air.

Bomb-shells are spherical cases of metal, fitted to be discharged by cannon, and containing a central charge of gunpowder, with an external charge of substances fitted to spread and inflict injury on the explosion of the powder, which is ignited by a fusee. The bombs also spread combustion where they alight.

Of *fixed fireworks*, or those whose motion is confined to a spot, jets, wheels, suns, trees, lances, spirals, revolving suns, double or Catherine wheels (two suns in one axis, revolving opposite ways), and many other beautiful contrivances, are now common exhibitions. In all preparations of a pyrotechnic nature, nitre, sulphur, charcoal, and gunpowder, are the chief ingredients. By means of spirits, gums, resins, and oils, the quality and duration of the light are modified, and the principal articles of that description in use are alcohol, bitumen, camphor, wax, turpentine, lard, and the like. Again, the colour of the fire, on which so much of the splendour rests, is modified by employing other articles. Copper-filings and sal-ammoniac give a greenish tint to flame; zinc, a fine blue; amber, and very dry common salt, a yellow; lampblack produces a deep red with gunpowder, and a pink with nitre in excess; camphor gives a fine white; lycopodium gives a rose colour; and sulphate of strontia, a beautiful purple light.

Instantaneous Matches, commonly known as *Lucifers*, are nearly all made of one substance—the chlorate or oxymuriate of potass. Dr Ure's formula for making the matches is as follows:—Thirty parts of the chlorate, in fine powder, are to be mixed gently with a knife upon paper with ten parts of very fine sulphur, eight of sugar, five of powdered gum-arabic, and enough of powdered vermilion to give a rose-tint to the whole. The chlorate, gum, sugar, and vermilion are then gently but well mixed, after which as much water as will make a thin paste is added, and then the sulphur is thoroughly mixed with the whole.

Of the numerous *fulminating powders* known to chemists, none, comparatively speaking, has any economical importance, except the fulminate of mercury, which is used for *percussion-locks*. The formula for the manufacture of the fulminate is as follows:—Dissolve 100 parts of mercury in 1000 parts of nitric acid, and add the solution to 830 parts of alcohol, a large vessel being used. A gas rises, which must be allowed to escape, and at a distance from flame. When the effervescence ceases, the contents of the vessel are to be poured out on a large double paper filter in a glass funnel, and cold water thrown over it till the drainings no longer redden litmus paper. The powder adhering to the vessel is also to be placed on the filter, with a little water. The superfluous acid thus washed away, the powder of fulminate of mercury, adhering to the filter, is lifted away, and opened out on plated copper or stoneware heated by steam. The powder, when dried, is in the form of small gray crystals, and is then to be packed in small parcels, and kept close from the air in bottles or boxes. Two and a half pounds of the fulminate will charge 40,000 percussion-caps. The preparation consists in grinding the fulminate upon marble with 30 per cent. of water, adding six parts of gunpowder for every ten of the fulminate. A dough is obtained which, when dried in the air, is introduced in small fixed portions into the bottom of the percussion-caps.

FICTILE MANUFACTURES.

WE employ the term *fictile* (*fingo*, *fictum*, to fashion) to comprehend all those arts which, like that of the potter, involve the moulding or fashioning of crude materials into determinate forms. Thus, with some degree of latitude, earthenware, porcelain, glass, bricks, tiles, mosaic tesseræ, cements, artificial gems, and the like, may be designated FICTILE FABRICS, in contradistinction to those of woollen, linen, silk, cotton, and other vegetable and animal fibre, which are strictly TEXTILE. The subjects thus embraced are numerous and important; of scientific importance, as involving at every step the deductions of chemistry and the principles of taste; and economically so, as elaborating from the crude and apparently worthless materials of the soil an almost infinite variety of articles of utility and elegance. Our limited space precludes the idea of a minute account, and restricts us merely to the leading features of the manufactures in question.

EARTHENWARE.

Pottery may be generally defined as the art of making vessels from clay, or from other mineral substances ground and rendered plastic like that body. The manufacture of porcelain or china is not included in this definition, inasmuch as it is semi-vitrified, and becomes translucent in the kiln. The fabrication of earthenware—that is, mere sun-dried or fire-dried vessels of clay—seems to have been one of the earliest of human arts; but pottery with a painted glaze was unknown till about the ninth century, when it was first attempted by the Arabs in Spain. Soon after, it found its way into the island of Majorca, where considerable progress was made in the art. From Majorca it was introduced into Portugal, Italy, and France, and thence into Holland. In the seventeenth century, a pottery was established at Burslem, in Staffordshire—at which, however, only the coarsest articles of brown ware were manufactured. Subsequently, the glazing of this ware by the vapour of salt—obtained by throwing handfuls amongst the heated articles in the kiln—was introduced by Mr Palmer; and in this state the manufacture continued till 1690, when two Dutchmen of the name of Elers commenced at the same place the fabrication of red unglazed porcelain, of black or Egyptian ware—the tint of which was produced by manganese—and of brown ware of a higher glaze and finish than had hitherto been produced in England. Some years afterwards, Mr Astbury was led by accident to attempt the admixture of ground flint with the finest white clay—a composition which yielded not only a finer and whiter, but a more durable ware than had previously been manufactured. It is to the late Josiah Wedgewood, however, that Britain is mainly indebted for the vast improvements which have taken place since the middle of last century in this department of her manufacturing industry. It was he who erected the first large factories in Staffordshire, and who, from his extensive chemical and mechanical knowledge, conjoined with correct taste, has made the stoneware manufactures of this country superior to those of every other.

The best clay for pottery manufacture is obtained in Dorsetshire, and another of a quality somewhat inferior is found in Devonshire. These clays are both well suited for the potter, being easily worked, standing the fire well, and becoming very white when burnt. When dug, the clay should be cleansed as much as possible with the hand, and freed from stones. At the factory, it is cut to pieces, and put into a cast-iron cylinder, about four feet high and twenty inches in diameter. An upright shaft or axis revolves in this cylinder, from which knives radiate in all directions, being so placed that the shaft with the knives attached somewhat resembles a screw. In the sides of the cylinder, knives are also fixed, which reach nearly to the shaft, and remain inactive. When the shaft moves round, the active blades cross the passive, and operate like shears in cutting the clay, which is by this process reduced to a fine pulp. The external appearance of the machine much resembles the 'pugging-mill' in fig. 7. When well ground in this manner, the clay is of the consistence of cream, and is run off through sieves of wire, lawn, and silk, so that none of the grosser parts may enter into the composition of the ware. This clay-cream, or *slip*, as it is termed, is then diluted to a standard density, and set aside in cisterns, to be used as required.

The clay thus prepared possesses remarkable plasticity; it is sensitive to the slightest pressure, and retains any form or impression given to it. But this high degree of plasticity brings with it sundry inconveniences: thus, in the firing, the articles are apt to crack, and also to become distorted. This distortion does not arise, it is supposed, merely from the evaporation of the water, but from the tendency of the particles to assume their normal condition, out of which they were forced by the processes of pressing and twisting, or 'throwing,' to which the clay is subjected. To prevent this cracking and distortion, it is necessary to add some silicious substance, incapable of contraction, to the clay. Ground flint is most commonly used for this purpose. It is prepared by cleaning the flint found imbedded in chalk, subjecting it to a red heat, and throwing it in this state into water, by which it becomes comparatively soft. It is then broken by being placed under upright shafts, which move up and down in a frame, and are called *stampers*. The broken flint is next transferred to the flint-mill, which consists of a strong wooden tub, built round a circular bottom, composed of flat pieces of hornstone. On the top of these, similar flat stones are laid, which are attached to, and driven by, strong wooden arms projecting from an upright shaft in the centre of the box. Into this tub the flint is put, and a stream of water is constantly running in, which greatly facilitates the grinding. In fig. 1, *a*, *a* represent the revolving arms, and *b*, *b* the stones fixed to them. When the flint is reduced to about the consistence of cream, it is passed through sieves, in a manner similar to the clay.

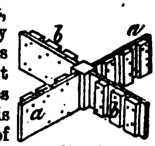

Fig. 1.

The flint and clay liquids being properly prepared, they are next mixed together in such proportions that the flint powder will be to the dry clay as one to five or six, according to the plasticity of the clay. Sometimes a little Cornish stone is also added; and the following are the proportions generally adopted in one of the principal Staffordshire factories for what is designated *cream colour*:—Silex, or ground flint, 20 parts; clay, 100 parts; and Cornish stone, 2 parts. This mixture is put into oblong stone-troughs, called *slip-kilns*, bottomed with fire-tiles, and placed above a furnace flue. Heat is then applied, and the water gradually evaporated, the liquid being constantly stirred during the operation. By this process, the mixture is formed into a fine uniform doughy mass, which is cut into pieces, and heaped together in a damp cellar, where they lie for the space

of about six months. The clay here becomes black, exhales a fetid odour, and undergoes a slight degree of fermentation, during which carbonic acid gas and sulphuretted hydrogen are disengaged. This improves both the colour and texture of the clay, and tends to bring it to a homogeneous mass. The longer the clay-paste is kept, the finer it becomes in the grain; and vessels made from it, when old, are not so apt to crack as those formed from newer paste.

The process of firing, as generally carried out, is a very wasteful one as regards the expenditure of fuel, and is attended with inconveniences. In view of these, more perfect processes have been introduced to get rid of the superfluous water: amongst others, we may notice the screw-press, and filtration by means of a vacuum. The most recent plan, and the most satisfactory in its results, is the adaptation of the hydro-extractor, or the centrifugal drying-machine, used in drying wet calicoes, &c. This consists of an outer case, in which a circular vessel with perforated sides revolves at a high velocity, a space being left between the two vessels. The clay is put into the inner vessel, which is set in motion; the centrifugal force generated has the tendency to throw the mass out of the vessel, but this being prevented by the sides, it is pressed forcibly against them, and the moisture is forced through the apertures, and falls into the space between the two cases. Such is the evaporative power of this contrivance, that a ton of clay is reduced to the necessary state of dryness by a revolution of three or five minutes.

To assist in forming the clay into a fine mass, the operation of sloping or wedging is performed at intervals during the period the clay is lying to ferment. This consists of slicing the clay with a spade, and dashing the slices together so as to expel the air which lodges in the mass. This process in large establishments is aided or performed by passing the clay through a mill. The last process previous to the throwing is the 'slapping,' which is performed by cutting masses into portions by means of a wire, provided with handles at its extremities, and dashing the pieces together again, care being taken to make them join parallel to each other; if this is not attended to, the grain being disturbed, the pieces are likely to crack during the process of baking.

The clay, being thus completely kneaded, is put upon the potter's wheel (fig. 2), where it is formed into articles of various shapes. This lathe consists of an upright iron shaft, the lower point of which turns in a socket, and the upper is fixed in a broad wooden disk. Near the top, the shaft passes through a socket attached to the framework of the lathe. In the centre is a pulley, with grooves of different circumferences, by which the speed of the shaft can be increased or lessened as circumstances require. This shaft is driven by a fly-wheel, from which an endless belt passes to the pulley. The clay is weighed

Fig. 2.

out and handed to the workman at the lathe, called the *thrower*, who dashes the mass upon the revolving wooden disk. He then dips his hands frequently into a dish of water placed beside the lathe, and pressing the clay with both hands, it gradually assumes an irregular conical form. By pressing one hand upon the top of this cone, it is again flattened down to a cake, by which operation all air-bubbles are extricated. He next lessens the speed of the shaft by shifting the belt from a small to a larger groove in the pulley, and forms the clay into the shape of the vessel required. This operation is called *throwing;* and when performed, the vessel is cut off from the disk by a wire attached at each end to a piece of wood. The vessel is then allowed to dry gradually, until it arrives at a certain point called the green state; after which it is put upon a turning-lathe, similar to that used by the worker in wood. Here it is turned to its proper shape by a sharp tool, which also smooths it, and after this, it is burnished with a steel surface.

In the green state, also, are attached handles and other appendages to vessels, this being the point at which the clay possesses its greatest tenacity, till it is burned. Handles of tea-pots, &c., are formed by squeezing the dough through different shaped orifices, which, as it issues, is cut into proper lengths, and bent into the desired forms. These being formed, are attached to the vessels by a paste called *slip*, and the seams are smoothed off with a wet sponge. The ware is next placed in an apartment heated to about 90° Fahrenheit, and fitted all round with shelving. When completely dry, they are rubbed over with hemp, and are then ready for the baking-kiln.

The articles made in the manner above described are all of a round form; but there are many which are of a different shape, and require a different process in the manufacture. Oval-shaped vessels are formed by what is called *press-work*, which is done in moulds made of plaster of Paris. One half of the pattern is made in the one side of the mould, and the other half in the other side. The parts are formed to fit each other exactly, and are joined in the same manner as the handles are to vessels. Imitations of flowers and foliage, and all delicate pieces of ornamental ware, are *cast* in moulds of plaster of Paris. The clay is poured into the mould in a thin state, and is there left for a certain time.

The plaster absorbs the water of that portion which lies nearest to it, and solidifies the mixture of clay and flint; the central fluid portion is then poured out, and the film or coating of clay left to dry. Another portion of fluid-clay and flint is then poured in, which is passed through the same process as before. The mould is placed in a stove, and after being dried, is touched up and rendered perfect in outline by a modeller.

Plates, saucers, wash-bowls, &c., are made by the process called 'flat-ware pressing.' A mould, *bb*, fig. 3, is made, which gives the outline of the internal shape of the article; and a profile-plate, *cc*, that of the outside. The latter is mounted upon a frame or carrier, by which the depth can be adjusted so as to give any desired thickness to the material. The mould, *bb*,

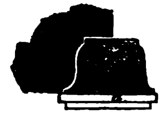

Fig. 3.

is placed upon a whirling-table, *aa*, and the clay is pressed down upon its surface, and moulded by the hands till it assumes the proper shape. Where an exact outline is required, the profile-mould is used. The thickness of the material is represented by the white space between the outlines *b* and *cc*, fig. 4.

When the ware is ready for the kiln, the articles are placed in baked fire-clay vessels called *sags* or *saggers*. These vessels are made of inferior clay, by the workmen during the intervals of their work, and are from six to eight inches deep, and from twelve to eighteen in diameter. The sags are packed full of the dry ware, and are then piled above each other in the kiln, the bottom of one sag forming the cover of another. These rude dishes are necessary, to prevent the ware from being suddenly and unequally heated, and also to protect it from the smoke and dust of the kiln.

Fig. 4.

Fig. 4 represents one method of packing articles in the sags. *aa* is a section of a sag, provided with projections on which the article, *bb*, is suspended. In the inside of this, a second article may be placed, as the jug shewn by the dotted lines. A second sag, as *dd*, is placed above the first, the bottom forming the cover or top to *aa*. In packing flat articles, as plates, little pieces of clay, of various shapes, as shewn at *a*, *b*, *c*, fig. 5, and known as cock-spurs, stilts, &c., are placed between the articles, as shewn at *d*, fig. 5; this keeps each article separate.

Fig. 5.

The body of a pottery-kiln is generally of a conical shape, covering and protecting from the weather the fire-kiln, which is circular, and provided with a domed top, as *aa*, fig. 6. The furnaces, six or eight in number, are placed equidistantly round the kiln, as *b*, *b*. The smoke escapes through the apertures made in the dome. The door for obtaining access to the interior is shewn at *c*. When the kiln is filled with the sags, it is built up, and fire applied to the furnaces. The heat is increased gradually, from the time the fire is put on, till the ware is found to be properly burnt. To ascertain this, the workman draws from the kiln what is called a *watch*, and if this is found to resemble in colour a previously burned vessel, he allows the kiln to burn a little longer, and then opens the doors of the furnaces carefully, so as to lower the heat by slow degrees. The burning, or *baking*, as it is called, usually lasts from forty to forty-two hours, after which the kiln is allowed to cool very slowly. When the ware is taken out of the sags, a child makes the pieces ring with the handle of a brush, used for dusting them, and then immerses them in the glazing material. The glaze is kept in a large tub, into which the articles are put by the child, and lifted out by a man, who shakes them in the air, and places them on a board, to be conveyed to the glazing-kiln.

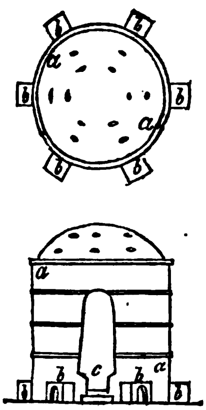

Fig. 6.

'Three kinds of glazes,' according to Dr Ure, 'are used in Staffordshire—one for the common pipe-clay or cream-coloured ware; another for the finer pipe-clay ware, to receive impressions, called *printing body;* a third for the ware which is to be ornamented by painting with the pencil. The glaze of the first, or common ware, is composed of 53 parts of white-lead, 16 of Cornish stone, 36 of ground flints, and 4 of flint-glass: of the second, 26 parts of white felspar, fretted with 6 parts of soda, 2 of nitre, and 1 of borax; to 20 pounds of this fret, 26 parts of felspar, 20 of white-lead, 6 of ground flints, 4 of chalk, 1 of the oxide of tin, and a small quantity of the oxide of cobalt, to take off the brown cast, and give a faint azure tint, are added. As to the ware which is to be painted, it is covered with a glaze composed of 13 parts of the printing colour fret, to which are added 50 parts of red-lead or litharge, 40 of white-lead, and 12 of flint; the whole having been ground together.'

The above compositions make a very clear, hard glaze, which is not affected by vegetable acids, and preserves its lustre for an indefinite time. When covered with the glaze, the vessels are put into sags, which have been previously glazed with a composition of 13 parts common salt and 30 parts potash. They are then put into the glazing-kiln, which is usually smaller than the biscuit-kiln, the sags being piled in the same manner as at the first burning. The heat of the glazing-kiln is very low at first, but gradually increases until it reaches the melting-point, when great care is necessary to prevent the temperature from suddenly falling. To ascertain when the temperature is high enough, balls of red clay, coated with fusible lead-enamel, are employed. When these balls become of a slightly dark-red colour, the temperature is sufficient to glaze ordinary pipe-clay ware. The fire is kept on for about fourteen hours, after which very little fuel is added, and the kiln is gradually allowed to cool. The vessels are again tried by being slightly struck by a small wooden hammer, when, if they ring freely, they are sound.

The colouring of pottery is performed either by what may be called painting, or by printing. The colours used in producing the *dipt* or *sponged* ware are of a very cheap kind, as it is only for common purposes that this material is employed. In dipt ware, the colours are dropped on before the ware is burned; and in sponged ware, when it is in the biscuit state. A black dip is made from manganese, ironstone, and clay-slip; a drab, by nickel and slip; a blue, by cobalt and slip; a yellow, by yellow clay alone, or by a compound of red and white clay; and a red, by a natural red or brown clay, which will burn red.

The colours used for painting and printing on ware are similar to one another, excepting that the colours for printing are more expensive; both, however, form an important and extensive part of the materials of a pottery. The manufacturers of earthenware are much occupied with the improvement of the variety and beauty of the colours, as well as of the patterns or styles that are produced, and hence a great emulation exists among those employed in the trade. The blue colour in *printing* is produced from cobalt, which is used with flint, ground glass, pearl-ash, white-lead, barytes, china-clay, and oxide of tin in reducing its strength; the brown, by ochre, manganese, and cobalt; the black, by chromate of iron, nickel, ironstone, and cobalt; the green, by chrome, oxide of copper, lead, flint, and ground glass; and the pink, by chrome, oxide of tin, whiting, flint, ground glass, and china-clay, which are mixed in various proportions, fused together at a high temperature, then pounded and mixed with oil. The colouring matter is ground upon a porphyry slab, with a varnish prepared from a pint of linseed oil boiled very thick, four ounces of rosin, half a pound of tar, and half a pint of the oil of amber. This transfer varnish is very tenacious, and requires to be liquefied by heat before being used.

The figure or design to be fixed upon the vessel is engraved in the usual way upon copper-plate, which is rubbed over with the colouring matter prepared as above, and the impression is taken upon a thin unsized paper made for the purpose. The printed paper is placed upon the vessel, and is rubbed with a roll of flannel about an inch and a half in diameter. After this the vessel is set aside for a little, to allow the figure to become fixed, when it is dipped in water, and the paper washed off with a sponge. The impression being transferred, the vessel is dipped in alkali to destroy the oil, and then immersed in the glazing matter. Printing above the glaze is performed by covering the copper-plate with the colouring matter as before, and brushing off what is superfluous. A cake of glue, stiff enough to be handled, is then laid upon the plate, which receives the impression of the figure. The glue cake must be very cautiously lifted off from the plate, and transferred to the surface of the glazed ware which it is intended to print. The same cake will answer for transferring a number of impressions, by simply washing its surface.

The ornaments on common stoneware vessels are made in relief in France, and hollow in England, by means of a mould in relief which is made to pass over the article.

These hollows are filled with a clay paste of the colour required, while the vessel is turning upon a lathe. Net-work and variegated decorations are made in this manner by passing different layers of coloured clay over each other.

In the finer pieces of ornamental ware, as porcelain casts, delicate net-work often covers part of the surface; this is put on by dipping actual lace in the slip, and passing it round the articles in a thoroughly saturated condition. The heat of the furnace destroys the thread, but leaves the clay thoroughly burnt. Messrs Boote, of Burslem, have patented, and introduced into successful practice, a process remarkable for the grace and beauty of some of its productions. It consists in inlaying one clay upon another—blue upon white, or white upon blue, for instance; certain effects and combinations of colour are thus easily effected, which before were impossible to be produced.

Metallic lustres, from gold, platina, copper, iron, &c., are produced by dissolving any of these metals in aqua regia, and applying it to the vessels. Over the metallic solution, a glaze composed of 60 parts of litharge, 36 of felspar, and 15 of flint, is put, and the vessels burned as before. These *lustres*, as the wares so coated are called, have a rich metallic appearance, and would be highly prized if they were not so cheap and common.

STONEWARE.

This is a ware intermediate between common earthen-ware and porcelain, and may be described as a coarse kind of porcelain, made from sandy clay, containing oxide of iron and a little lime, to which it owes its fusibility. The glazing is performed by throwing common salt into the heated furnace; this is volatilised and decomposed by the joint agency of the silica of the ware and of the vapour of water always present; hydro-chloric acid and soda are produced—the latter forming a silicate which fuses over the surface of the ware, and gives a thin but excellent glaze. The salt is not thrown in until the kiln has been raised to its greatest necessary temperature. Ware of this kind, we have said, is generally made of sandy clay and a little sand, to keep the body open, or less compact; but for large vessels, pot-sherd (which is ware that has been fired, and then ground) is employed, to render the body still more open and porous, and also to give it a capability of withstanding sudden heats or colds. This ware is much used for chemical purposes; it is exposed to the action of the flame during burning, whereas other kinds of ware are protected by saggers.

Stoneware of the Wedgewood colour is a semi-vitrified ware, which is not susceptible of a superficial glaze. It is composed either of barytic earths, which act as a flux upon the clay, and form an enamel, or by the clay being rubbed over with a compound vitrifying paste. Semi-vitrified ware undergoes an operation called *smearing*, by which the vessels do not require to be immersed in glaze. They are merely put into the glazed sags, which communicate by reverberation a lustre nearly equal in brilliancy to glaze itself. Messrs Green, of Lambeth, have produced, in stoneware, possibly the largest vessels yet manufactured; these are designed for breweries and distilleries, and are sometimes of enormous dimensions.

PORCELAIN.

Porcelain or china is a fine-grained, compact, very hard, faintly translucent ware, of which there are two kinds—one called hard, and the other tender or soft. *Hard* porcelain is composed of a clay containing silica, which is infusible, and preserves its whiteness in a strong heat, and of a flux consisting of silica and lime. The glaze of this ware is earthy, and admits of no metallic substance or alkali. *Tender* or soft porcelain consists of 'kaolin, Cornish stone, and bones.' It is glazed with artificial glass, into the composition of which silica, alkalies, and lead enter.

Kaolin-clay is the largest ingredient in porcelain ware. It is composed of alumina and silica, and is obtained in large quantities in China, Germany, France, and in the county of Cornwall in England. Kaolin is very friable in the hand, and is with difficulty formed into a paste or dough which will bear to be worked. That found in Cornwall is whiter than the foreign clays, and more unctuous to the touch. It is a decomposed felspar—one of the constituent minerals of granite—which has accumulated in vast quantities in certain localities, having been no doubt washed down by rains from the weathered and exposed surface of granitic rocks. When the kaolin or china clay of Cornwall is mixed with alluvial matter, it is broken into lumps, and thrown into a running stream; this carries off the firm particles into catchpools, where the sediment is allowed to settle, and the water is drawn off, leaving the clay.

As the processes which the material goes through in its manufacture into the various forms of porcelain ware, very closely resemble those which we have already described in our remarks on pottery or earthenware, it is unnecessary here to repeat them.

Among recent inventions in the manufacture of porcelain, may be mentioned Parian or statuary porcelain, the beauty of which will doubtless be familiar to most of our readers through the medium of the reproductions of modern sculpture, on a reduced scale, by the celebrated firm of Minton & Co., and Messrs Copeland. The use of a soft felspar instead of the Cornish stone, is that which chiefly imparts the peculiar effect. Great care is necessary in producing articles of this material: they are generally cast in moulds, in a number of pieces; and as the process of firing contracts the size to the extent of one-fourth, great skill on the part of the artist is called for. Unglazed porcelain has the appearance of marble or alabaster, and is much used for ornamental articles and statuettes. It is known by the name of 'biscuit.' In the adaptation of this material, the Sèvres manufactory in France has been long distinguished. The English manufacturers are, however, fast following them, if not already equal. Messrs Minton have succeeded in introducing specimens of this manufacture, which, for their 'freshness of effect and excellent taste,' have attracted great attention. Parian porcelain far exceeds in beauty and softness the ordinary porcelain biscuit; the effect arises from the light penetrating to a certain depth, while in biscuit the light is reflected at the surface, giving it a 'cold appearance.'

A variety of hard porcelain has been introduced by Messrs Minton for the dishes, &c., used for chemical purposes, and with such success, that the monopoly enjoyed by the continental firms is likely to be, if it has not already been, broken through.

In painting on porcelain, the same colouring materials are used as those employed in colouring glass or earthen-ware. In all the more delicate patterns, they are laid on with a camel-hair pencil, and generally previously mixed with a little oil of turpentine. Where several colours are used, they often require various temperatures for their perfection; in which case those that bear the highest heat are first applied, and subsequently these that are brought out at lower temperatures. This art of painting on porcelain, or *in enamel*, is of the most delicate description: much experience and skill are required in it, and with every care, there are frequent failures; hence it is attended with considerable expense. The gilding of porcelain is generally performed by applying finely divided gold mixed with gum-water and borax; on the application of heat, the gum burns off, and the borax, vitrifying on the surface, causes the gold to adhere: it is afterwards burnished with bloodstone, agate, or other polishers.

Porcelain vessels are very brittle, and are easily damaged, which accounts in some degree for the high price at which they are sold. It is calculated that, after being manufactured, one-third of the articles are found

damaged, most of which takes place in the kiln. English and foreign porcelains differ considerably in their composition, which accounts for their difference of transparency, brittleness, and fitness for chemical purposes.

'There are some considerable manufactories of pottery-ware in the north of England, and one or two in Yorkshire; but the principal site of both porcelain and pottery wares is in the modern borough of Stoke-upon-Trent, which contains a population of about 70,000 persons engaged directly or indirectly in these manufactures.' The principal seats of porcelain manufacture in continental Europe are Sevrès near Paris, Tournay in Flanders, Dresden, Berlin, and Florence; the wares of Sevrès being as yet unequalled in their translucency, glaze, and gilding, and in the elegance and taste displayed in their shape and figure-paintings.

BRICKS—TILES—DRAIN-TUBES.

Bricks formed of tempered clay, and artificially hardened by heat, may be termed a species of artificial stone. They have been used for building purposes from a very early period in the world's history. Anciently, bricks were of two kinds—sun-dried and fire-burnt. The former were much used in the buildings of Egypt and Babylon—they are still used in the East. The humid climate of England, however, requires a more careful and certain hardening than that which the sun gives; hence the use of fire for this purpose. It was not till after the Norman Conquest that bricks were much used in this country. It was, however, in the reign of Henry VIII. that brick as a building material attained a high repute. Its use was mostly confined to the erection of large buildings, and in these a great amount of decorative effect was often produced. Mr Dobson, in his excellent treatise on *Bricks and Tiles* (London: Weale), refers particularly to the decorative details of the manor-house at East Barsham, and of the parsonage-house at Great Snoring as worthy of notice. He also gives an illustration of ornamental brick-work as exemplified in a house, No. 43 St Martin's Lane, London. Up to the period of the Great Fire in London, the dwelling-houses were chiefly composed of wood; after that event, the danger arising from this cause was obviated in some measure by the compulsory use of bricks, not only for the walls, but for the ornamental parts of the house. From this cause may be traced the erection of many fine specimens of brick-work throughout the metropolis. The minute tracery-work which abounds in many specimens, appears to have been executed by tools after the erection of the walls.

It is in England that the manufacture of bricks is of such importance; in Scotland, it is less practised, owing to the ease with which stone well adapted for building is obtained.

Up to the close of the last century, bricks were untrammelled by the Excise; by the 24 Geo. III. c. 24, a duty of 2s. 6d. per thousand was imposed on bricks of all kinds. By the act 34 Geo. III. c. 15, this was raised to 4s. The uniformity, however, of the imposition was done away with by the division of bricks into 'common' and 'dressed,' different rates of duty being laid upon each kind. By the same act, tiles were taxed. By the act 3 William IV. c. 11, 1833, the duties on tiles were repealed; and in 1835, the duty on common bricks was raised from 5s. to 5s. 10d. per thousand. The distinction in bricks as to size and quality was in 1839 done away with by the act 2 and 3 Victoria, c. 24, by which 5s. 10d. per thousand of duty was charged, the only condition imposed being, that each brick was not to exceed 150 cubic inches. The size of an ordinary building-brick was nine inches long, four and a half broad, and three thick. This new act gave a great impetus to the manufacture, as by it many restrictions as to the shape were removed, and ornamental bricks, &c., allowed to be made. Still, however, the 'building interests' felt the Excise restrictions upon the article to be exceedingly harassing in their operation, and depressing in their influence upon the progressive improvements which would otherwise have been introduced into the manufacture. In consequence of their repeated representations, and the advocacy of the journals devoted to their interests, the duty on bricks was wholly repealed by a recent act, and the trade left free.

The increase in the quantity of bricks annually manufactured has been very marked during the last half-century. In 1821, the number in England and Scotland amounted to nearly a thousand millions; in ten years it had increased to twelve hundred millions; and in other ten years, to nearly eighteen hundred millions. The rapid increase of railways has had a great influence in extending the trade: Mr Dobson calculates the quantity required for each railway bridge at 300,000; and for a mile of tunnelling, at fourteen millions.

The common superficial clay, which is so liberally spread over our island, must be familiar to every one. It is of various colours—yellow, red, or bluish, according to the amount of iron oxide which it contains—is more or less mixed up with sand and fragments of rock, and when softened, becomes plastic and tenacious. What is chiefly necessary is a due admixture of alumina and silica—that is, clay and sand; for though pure clay may be made into extremely hard bricks, they are apt to shrink and crack in the burning; while too much sand renders them brittle and friable. As to the presence of a little lime, magnesia, or oxide of iron, it is rather liked than otherwise, these materials giving agreeable colours to the finished article. For bricks, slabs, crucibles, &c., which have to resist the action of fire, some of the coal-measure or stratified clays are generally had recourse to; these, from their greater purity, and a certain percentage of silica, being susceptible of a more thorough baking. In England, the Windsor, Stourbridge, and Welsh fire-clays are esteemed the best—the latter yielding those large square slabs employed in the construction of drying-kilns, brewers' coppers, sugar-boilers, smelting-furnaces, and the like.

From the process of brick-making varying in different localities, our space compels us to give merely a general notion of the manufacture. Bricks are of different qualities. Thus, the *malms* of the London bricklayer are of a yellowish uniform colour and texture, prepared by an admixture of ground chalk; *seconds* are those less uniform in colour and texture; *cutters* are those made so soft, as to be cut into form for arches of windows; *fire*-bricks are prepared to withstand the heat of fires and furnaces, and of such there are varieties known as *Welsh lumps*, *Windsors*, &c.; *paving*-bricks, made for the purpose their name implies; *compass*-bricks, of a circular shape, for lining walls and chimneys; *Dutch clinkers*, at one time imported from Holland, but now made in England, a compact variety often used in stables, about six inches long, three broad, and only one in thickness. The *floating* bricks known to the ancients, and recently revived by M. Fabroni, are composed of a silicious or infusorial earth, commonly known as fossil or mountain meal.

After having decided on the locality of the brick-field, the first process is the removal of the earth-covering. The clay or brick-earth is then dug up, and placed in heaps, and turned over, to expose the masses to the mellowing action of the winter air and frost. The next process is tempering the clay, that is, preparing it in the form of a homogeneous paste for the moulder. This is still effected in many districts by hand, turning it over and over, and treading it with horses or men. In the improved processes, tempering is effected by the use of revolving rollers, between which the clay is passed; or by what is termed a pug-mill. This consists of an upright conical tub, the small end downwards; in which a shaft, fitted with projecting knives or cutters, is made to revolve by horse-power. The knives knead and cut the clay, and force it through the bottom of the mill,

where it is cut into lumps, and laid aside till required. Fig. 7 shews an improved form of pug-mill, known as

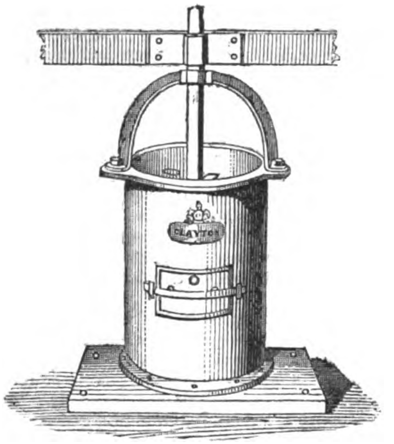

Fig. 7.

Clayton's Archimedean knife pug-mill. Great care is taken at the outset to free the clay from all stones, pebbles, &c.; the presence of one of which, even of small dimensions, will cause the brick to crack in drying. Where much gravel is mixed with it, which no amount of hand-picking could remove, it is washed, and reduced to the consistence of a fluid; in this state, it is passed through a grating, which retains all the gravel, and allows the fluid clay to pass.

Where limestone abounds in clay, it is ground between rollers, which crush the limestone; of which a small piece, if left, will cause the brick to have air-holes made in it while burning, from the carbonic acid gas evolved by the heat.

Where marl is used for malm bricks, it is ground to a pulp in the wash-mill, and mixed with lime in the shape of a thick liquid. The whole is then placed together, and allowed to become firm enough to bear walking on its surface; it is then covered with fine ashes, and allowed to stand all the winter till spring, when the whole are well mixed together.

The next process is the moulding. The mould consists of a frame the size of the brick, without top or bottom, as *aa*, fig. 8. In the improved form of solid bricks, indentations, as *c*, are made in the upper and under faces of the brick (*b*, fig. 8). These form a 'key' to the mortar, securing efficient bond. To form this indentation, projections are made in the bottom of the mould and in the top. The moulder works at a bench; and his art consists in dashing in a lump of the tempered clay so as completely to fill up the mould, the superfluous clay being dexterously taken off with what is called the *strike*. To prevent the clay adhering to the mould, it is either dipped in water, or sprinkled with sand: if the latter, it is termed 'pallet-moulding;' if the former, 'slop-moulding.' In slop-moulding, two moulds are required, as the mould with its newly made brick is carried off by the attendant boy to the drying-ground, where the brick is deposited, the moulder the while forming another brick in a second mould, which is finished by the time the boy returns with the first.

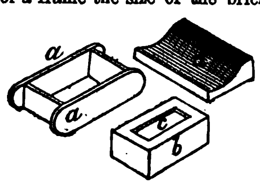

Fig. 8.

In pallet-moulding, one mould alone is used, the bricks being turned out on a pallet when made, and taken by the boy in a hack-barrow to the drying-floor. By slop-moulding, a man can make 10,000 per week; while by pallet-moulding, he can make as many as 36,000; in the latter case, however, the moulder has an assistant.

The next process, or that of drying, is one which requires considerable attention. 'The great point,' says Mr Dobson, 'to be aimed at is to protect them against sun, wind, rain, and frost, and to allow each brick to dry uniformly from the face to the heart.' The drying is sometimes effected under cover; but more frequently the 'hacks' are built in the open air, and covered with various substances, as straw, tarpaulin, &c.

The last process is the burning, which is performed either in *kilns* or in *clamps*—the latter being large square piles of bricks skilfully built up, with layers of fuel between, called *breeze*, and also with flues filled with coal, cinders, and wood, to facilitate still more the process of combustion. Baking in kilns, however, is preferable, as there is not only less waste, and less fuel consumed, but the bricks are sooner ready for the market. 'The kiln,' says Dr Ure, 'is usually 13 feet long by 10½ feet wide, and about 12 feet in height. The walls are one foot two inches thick, carried up a little out of the perpendicular, inclining towards each other at the top. The bricks are placed on flat arches, having holes left in them resembling lattice-work; the kiln is then covered with pieces of tiles and bricks, and some wood put in to dry them with a gentle fire. This continues two or three days before they are ready for burning, which is known by the smoke turning from a darkish colour to transparent. The mouth or mouths of the kiln are now dammed up with pieces of bricks piled one upon another, and closed with wet brick-earth, leaving above it just room sufficient to receive a fagot. The fagots are made of furze, heath, brake, fern, &c., and the kiln is supplied with these until its arches look white, and the fire appears at the top; upon which the fire is slackened for an hour, and the kiln allowed gradually to cool. This heating and cooling are repeated until the bricks are thoroughly burned, which is generally done in forty-eight hours. One of these kilns will hold about 20,000 bricks.'

Clamp-dried bricks require to be thoroughly dried previous to burning. Where kilns are used, the heat can be regulated so nicely that comparatively damp bricks may be put in, which are first dried by a gentle heat. In the clamp, as the heat is got up almost immediately, it would cause damp bricks to fly in pieces.

Tiles are prepared much in the same way as bricks; only, from their being thinner, and of a more intricate form, they require to be made of finer and tougher materials, and are always burned in kilns. They are of different kinds, according to the use to which they are applied—as *plain* and *pan* tiles, *ridge* tiles, &c. In fig. 8, *d* shews the form of the mould for a 'pan-tile.'

Machines are sometimes used for the purpose of

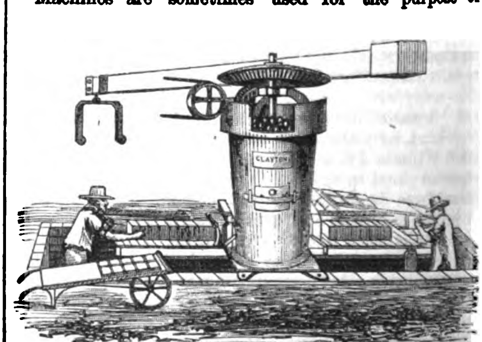

Fig. 9.

moulding the bricks. They are, however, chiefly available in cases where a large number of bricks are to

be made. For small brick-works they are far from being economical, the cost of moulding being a very small proportion to the other items of brick-making. The best known machines are those of Clayton; a solid brick-making machine of this maker is shewn in fig. 9. Mr Prosser of Birmingham has introduced a patent brick-making machine. The clay is used in a state of dry powder. This being put into metal moulds, and subjected to an enormous pressure, the particles cohere with great force, and can be immediately carried to the kiln.

Drain tiles and tubes are always made by machine: the former are of a horseshoe shape, and are made by rolling out the clay into sheets between two cylinders, and thereafter cutting out the necessary oblong parts, and bending them into the proper shape by an ingenious assemblage of endless chains, levers, pulleys, &c. The tubes are made by pressing clay from a cylinder through dies of the size and shape of the tube wanted, the cutting off of the lengths being also effected by the machine. Hollow bricks, now so much used, are also made by machinery. In fig. 10 we give diagrams of the dies used for forming various hollow articles: *a* is the die for the hollow brick shewn in perspective at *e*; *b*, a die for a circular drain-tube; *c*, a die for a drain-tube with flat bottom; and *d*, a die for a recently introduced form of hollow earthenware step for fire-proof staircases. In all these, the clay is forced through the spaces represented white; the shaded parts being the iron portion of the dies. An immense variety of machines have been introduced for this branch of the earthenware manufacture.

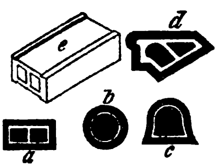

Fig. 10.

For architectural decorations, figures, vases, &c., on a large scale, a variety of argillaceous compounds are now in use, the principal of which is known by the name of *terra cotta*—literally, baked clay. This composition consists of pipe or potters' clay, a fine colourless sand from Ryegate, and pulverised potsherds. These are worked into a homogeneous paste, which is modelled or cast into the figure required, then slowly dried in the air, and ultimately fired to a strong hardness in a proper kiln. Tobacco-pipes are made of a finely ground white plastic clay (to which they have given the name), chiefly found in the Isle of Purbeck in Dorsetshire. This clay being worked into paste and dough, in the same manner as the finer sorts of potters' stuff, is next rolled into cylinders for the stems, and into balls for the bowls. These are then pressed to the desired form in metallic moulds, and pierced with a wire; dried for a day or two; scraped, polished, and dipped; and ultimately fired in a baking-kiln for ten or twelve hours. A clever workman, aided by a boy, can easily make from five to six gross of plain pipes per day.—For *Meerschaum*, see MINING—MINERALS.

ENCAUSTIC TILES—TESSERÆ—MOSAICS.

The term *mosaic* is said to be derived from the Greek word *mousaikon*, elegant or polished; and is now applied to the art of imbedding or inlaying in a cement fragments of different coloured substances, so as to produce the effect of a picture. This art was practised at a very early period, and was introduced into Italy by the Byzantine Greeks. Magnificent specimens are to be seen in St Peter's at Rome, and in the chapel of St Lawrence at Florence, where precious marbles, agates, jaspers, avanturines, malachites, &c., constitute the coloured tesseræ.

The ancients applied mosaics chiefly to pavements, for which they are admirably adapted. Specimens of highly decorated pavements are also frequently met with in the grand ecclesiastical structures of the middle ages. Such is the beauty, as well as the durability, of this species of pavement, that attempts have frequently been made in this country to revive the art; and recently Mr Minton has succeeded in carrying out the patent process of Mr Wright for a new style of mosaic. Some of the most elaborate subjects, as coats of arms, are so finely executed, that it is difficult, at a cursory glance, to get rid of the idea that they are the fine products of the pencil. Great care is taken in the preparation of the clay, it being repeatedly washed and purified, and passed through fine sieves. The pattern is first carefully modelled in clay, the parts constituting the device being depressed about a quarter of an inch, and from this a cast is taken in plaster, and placed in a metal frame. To make a tile six inches square, one $6\frac{5}{8}$ inches is made, in order to allow for contraction. A sheet of fine clay is pressed upon the plaster-cast, and a sunk impression is thus obtained. The thickness of the tile is made up by coarser clay, after which it is placed in the press, and the proper degree of solidity given to it. When the pattern is of different colours, the following process is followed. The clays of different colour are poured into the indented parts of the pattern, covering the whole surface of the tile, and are allowed to dry. The surface is then scraped, so as to expose the pattern, and the tile is placed in the drying-house for a fortnight or three weeks, and finally subjected to an intense heat for sixty hours, which brings out the colours with great brilliancy.

A species of ornamental tile is now made after the manner of the Alhambra. In forming the tiles, the clay is pressed in embossed moulds, which give the various grooves and indentations. They are then fired; and after this process, the hollow parts are filled up with enamels of various colours, which, after firing, produce a very brilliant effect. The pattern being in low relief—a distinguishing characteristic of the Alhambra style of ornamentation—the tiles are capable of being used either for floors or the covering of walls. A beautiful exemplification of this style may be seen in the Alhambra Court at the Crystal Palace of Sydenham.

One way of forming slabs for mosaic pavement is this: Plain self-coloured tiles, or tesseræ, are made of powdered clay, subjected to great pressure in strong steel dies, which gives uniformity of size and shape. They are then formed into slabs of any size required, by placing them, when being fired, on a smooth platform, with the face downwards, the arrangement being such as to produce the pattern intended. In this position, liquid cement is poured upon them, which unites them together.

There is a new style of mosaic pavement, manufactured by Alfred Singer & Co., composed of tesseræ of vitreous clays. The clay, after due preparation, and colouring with metallic oxides, is formed by the machine into long thin ribbons about $\frac{3}{8}$ inch thick, and three or four feet long; out of these the various patterns or shapes of tiles required are cut by machinery, so as to obviate the necessity of chipping to make them fit. A number of these are laid with their face downwards, to form the pattern or design, and the whole united to form a slab by pouring liquid cement over the baked surface.

Roman Mosaics.—The fabrication of these pretty ornaments is altogether a different art. The following is an account of the peculiarities of the manufacture, as given by M. Pistrucci, the chairman of the jury of the Great Exhibition on ceramic manufactures:—The mosaics which are made in these times are composed of pieces of glass, sometimes called *smalt*, and sometimes paste. They are made of all kinds of colour, and every different hue; and for large pictures they take the form of small cakes. For small works, they are produced in threads, varying in thickness from that of a piece of string to the finest cotton thread. Heaps of these, of all tints and colours, are prepared; a plate or slab of copper,

marble, or slate, is then provided, of the size and thickness required for the intended work. This slab is hollowed out so as to resemble the bottom of a box or a tray, to a depth proportioned to the work; this may vary from an inch to the eighth, or even the sixteenth of an inch, if the work is to be small. This hollow is then filled with plaster of Paris, well smoothed, on which the outline of the proposed design is very accurately traced, and an inked pen is passed over the outline, to preserve it. Very few tools are required by the workman; but for the large works, where comparatively large pieces are to be inserted, small sharp-cutting hammers are made use of for splitting the cakes and reducing them to their proper size and form. Pincers, also, of different forms are used, for placing them equally. In very small works, instead of hammers, sharp-pointed pincers are made use of, like those with which diamonds are taken up, and sometimes a small tool like a scarpello. The heat of an oil-lamp is required to enable the workman to draw out the strips of glass to the fineness he wants, even to that of a hair. When all this is ready, the first operation is to dig or scoop out, with a scarpello of the proper size, a small piece of plaster of Paris from the bottom of the box or tray, without injuring the outline; this is filled up with a kind of mastic, like that which is used to fix panes of glass in the sashes or frames of a window, and the required piece of smalt or glass is then pressed into the mastic or composition. In this way, step by step, and from day to day, repeating the operation of scooping out a small piece of plaster of Paris, and never losing sight of the outlines, they gradually fill up the whole tray. In works of considerable dimensions, the workmen place the tray or plate before them, as painters place the canvas on which they are painting, and have the original always close to them. For smaller works they sit at a table, as if writing, and generally keep their work flat on the table. . . . . When this operation is completed, it is passed over a stone made perfectly smooth, and cleaned of every kind of dirt. But as it will always happen that interstices, however minute, will be left more or less between the several small pieces of smalt inserted in the mastic, these are to be carefully filled up with heated wax, applied with hot iron implements from a pallet on which it has been prepared for the purpose; and much of the good effect and finish of the work will depend on the ability and care of the workman by whom this operation is performed.' The workman—named the *mosaiciste*—does not produce the design, or even trace it on the plastic; this is the work of a separate class, the designers. The manufacture of Roman mosaic has, we understand, been always confined to Rome, no other town or country competing with it. Of late, however, imitations have been produced in this country.

GLASS.

The origin of the glass-manufacture is involved in the greatest obscurity, and has given rise to much ingenious speculation, upon which little or no dependence can be placed. Glass beads have been found on the bodies of Egyptian mummies which are known to have been embalmed 3000 years ago. Pliny says that the art of glass-making was accidentally discovered by some shipwrecked Phœnician mariners, whose vessel was laden with fossil alkali, a component part of glass. On kindling a fire on the sand to prepare some food, and placing their cooking-vessels on pieces of the substance just named, the sand, by the agency of the fire and its union with the alkali, became vitrified; hence, according to this authority, the discovery of the art.

The first glass-manufactory of any note was established at the village of Murano, near Venice. The glass produced here was superior to any in Europe, and for a long time the principal supply was obtained at this place. The Venetians were long celebrated for making mirrors, which they brought to considerable perfection. Window-glass appears to have been made in England in the middle of the fifteenth century, but it was of an inferior description. In 1557, the finer sort of window-glass was manufactured at Crutched Friars in London. The first flint-glass was made at Savoy House in the Strand; and the first plate-glass for mirrors, coach-windows, and the like, was fabricated at Lambeth in 1673, by Venetian workmen, brought over by the Duke of Buckingham.

A glass-house is usually built in the form of a cone, from 60 to 100 feet high, and from 40 to 80 feet in diameter at the base. The furnace is placed in the centre of the building, and is generally of an oblong figure, although sometimes circular. Below the furnace is an arched gallery, extending right across the building, and terminating in folding-doors, large enough to admit a barrow for carrying out the ashes. In the sides of the furnace are apertures called working-holes, through which the materials are put into the pots, and the blowing-tubes inserted. In a crown-glass manufactory, the furnace generally contains from four to six pots; but this will altogether depend upon the size of the building. The stone used in constructing glass-furnaces must be of the finest quality; that called fire-stone, got from Coxgreen, in the neighbourhood of Newcastle, is considered the best for this purpose.

Crown-glass.

Crown or window glass is usually composed of alkalies, and fine white sand. The best sand for glass-making is that which contains most transparent particles, and this is found in large quantities in that brought from Lynn Regis in Norfolk, and the western coast of the Isle of Wight.

Up to a period dating thirty years ago, kelp, obtained by the burning of a certain sea-weed, was the alkali used in glass-making. But in 1792, Le Blanc discovered a method of converting common salt into carbonate of soda; thus affording to manufacturers a readily obtained and inexhaustible supply of alkali. From the introduction of this, a new epoch in the history of glass-making may be dated.

The base of all glass is that above stated, but to the alkali and the silica (sand), lime and other ingredients are applied. The lime, in due quantity, promotes the fusion, and improves the quality of the mass; but if too much is present, it renders the glass difficult to work, and subject to devitrification. Alumina, which is also sometimes added, and which is always accidentally present, renders the glass liable to devitrification. Iron, too, is present, and as this colours the glass, its effects are got rid of by the addition of manganese. When the soda is introduced in the form of sulphate, or Glauber Salt, charcoal is introduced, to decompose the salt. Arsenic is also added to decompose other ingredients. The proportion in which these various materials—as sand, soda, charcoal, chalk, manganese, and iron—are mixed, varies with circumstances, and according to the fancy of the manufacturer. To this mixture of materials, a portion of broken waste-glass, termed *cullet*, is added, to promote the fusion.

The pots in which these materials are placed, to be subjected to the action of the furnace, are all made by manual labour, being built up bit by bit, and occupy many months before being ready for use. They are made of the best Stourbridge clay, mixed with about one-fifth of ground potsherds, are carefully dried for months, and thereafter exposed to the action of the kiln. Their average duration is five to seven weeks. Flint and compound glasses are melted in *covered* pots, to protect the mass from the action of the flame and smoke which would bring about a chemical action, tending to precipitate in a solid state the lead and other metals used. The furnace in which the pots are deposited is circular in form, the fire-bars in which the fuel is consumed being in the centre, and nearly on a level with the floor of the glass-house. A series of subterranean

passages are placed at various angles with the main or transverse passage, which serves as the ash-pit, a supply of air being thus obtained from different directions. The pots are placed round the circumference, at regular intervals; one on each side of a flue. An aperture is left in the brickwork, in the space between two flues, through which the materials are passed to the pots. The heat is regulated to any degree of intensity, by opening or shutting apertures admitting more or less air to the grate bars.

The materials are introduced into the pots by means of an iron shovel, the pots being previously brought to a white heat. The aperture is then closed with a stopper, and carefully luted with clay. After subjection for some time to a high temperature, the whole become thoroughly fused, and enter into chemical combination; the silica uniting with the bases, soda, lime, &c. (see CHEMISTRY) to form silicates. On the mass subsiding, fresh materials are added till the pot is filled with the molten glass.

The pots last for periods of greater or less extent —some for two, three, and even twelve months, while some give way during the preliminary testing to which all are subjected. When they are worn out, or give way, the operation of removing them and substituting new ones is one attended with considerable labour and excitement, and being carried on under the action of an intense heat, always excites the surprise of the spectator. When kelp was used, the operation of 'fritting' was necessitated, which consisted in stirring the mass under the heat of a reverberatory furnace; by which partial decomposition and the burning up of various impurities were effected. This preliminary operation is now dispensed with, owing to the use of soda.

The pots being now full of melted glass, the material is ready for the operations of the workmen. An iron tube, six or seven feet in length, thicker at one end than the other, is heated and dipped into the liquid 'metal.' A portion of glass adheres to the end of the rod, which, being

Fig. 11.

allowed to cool a little, is again dipped in, and gathers more. The rod is then taken out, and hung perpendicularly, that the metal may be equally distributed on all sides, and also that it may be lengthened out beyond the rod. The metal is next rolled upon a smooth iron plate, called the *marver*, and afterwards blown out slightly, so as to resemble a pear in shape. The blower then heats the metal twice, blowing it out between the heatings, when it is brought to a globe shape. The glass is then allowed to cool a little, and a rod of iron, called the *punty-rod*, is attached to the side immediately opposite to the tube. This is done by dipping the end of the rod in the liquid metal, which adheres readily to the half-cooled glass, and the tube is detached by touching it with a piece of iron dipped in cold water, leaving an aperture in the glass about two inches in diameter. The glass is again put into the furnace until it has become sufficiently ductile to yield readily to any impression. The workman then twirls the globe round, slowly at first, but afterwards with great velocity, during which the aperture formerly mentioned gradually widens, until it reaches a certain point, when the globe suddenly flies open with a loud ruffling noise, and becomes a plane or circular sheet of glass, about fifty inches in diameter. This is an exceedingly beautiful operation, and requires considerable skill on the part of the workman. The circular motion is still continued, until the sheet is sufficiently cool to retain its form, when it is carried to the annealing-arch to be tempered. The punty-rod is detached by means of large shears, and the sheet of glass is lifted on a wide-pronged fork, and set up edgewise in the kiln. A kiln will hold from 400 to 600 sheets. When full, the mouth is built up, the fire withdrawn, and the kiln allowed to cool as gradually as possible. This process of gradual cooling is known by the name of *annealing*—a process without undergoing which, glass, as well as several of the metals, would be so brittle as to break on the application of the slightest force. The glass is then taken out, the circular sheet cut into halves, and assorted into different qualities, known by the names of *firsts*, *seconds*, and *thirds*.

The glass thus produced is very rarely indeed of the best quality: it is generally characterised by more or fewer 'defects.' But even where a faultless 'table,' as the circular sheet is termed, is produced, the mode of manufacture prevents sheets of large glass being obtained. The wavy concentric lines at one time characteristic of this glass, are now not so common, through improvements in the details of the manufacture. But the distinguishing peculiarity of this glass—its beautiful brilliancy—is highly prized, and has had a decided effect in enabling it to withstand the formidable rivalry of the sheet-glass manufacture, to which we now direct the reader's attention.

Sheet-glass.

The process we have described is altogether applicable to crown or window glass; the manufacture of sheet-glass is somewhat different. In making sheet-glass, the same materials are used as in crown-glass, the difference being in the manner of forming the sheet. When the metal is melted, the workman dips his tube into the pot, and when he has gathered a sufficient quantity of the liquid glass upon it, he places it in a horizontal position upon a hollowed block of wood. He turns the rod round in his hand, with the metal resting upon the hollowed block, which forms it into a solid cylindrical mass. Water is poured upon the block during this operation, to prevent the burning of the wood and the scratching of the glass. If the glass was only red hot, on coming in contact with the water, it would crack; but at the great heat at which it must be kept so as to be ductile, no injury takes place. When the metal is sufficiently formed and cooled, the workman blows into the tube until he perceives the diameter to be of the dimensions required, which depends upon the size of the sheet to be made. The metal is again put into the furnace, and when softened, the workman swings it round his head, re-heats, and continues to swing it, until the cylindrical mass has attained what he thinks a sufficient length. He then fills the tube with air, at a slight pressure, by blowing into it, and closes up the hole, so that none may escape; after which the metal is again put into the furnace, and as it becomes soft, the air bursts from the end opposite to the tube, leaving an aperture. The cylinder is now turned round very quickly, which renders it perfectly straight; and then, by applying cold iron to the end of the glass next the tube, a sudden contraction takes place, which separates the cylinder of glass from the iron tube. The cylinder thus formed is allowed to cool for about five seconds, and is then split up lengthwise by drawing a diamond along the inner side. The glass has next to be flattened, which is done by softening it in a furnace upon a smooth plate, where, as it begins to melt, it gradually opens, and is smoothed with a piece of charred wood. It is then carried to the annealing-furnace to be tempered, in the same manner as crown-glass. The method above

described of making sheet or cylinder glass was introduced, in 1842, from the continent by the Messrs Chance. These gentlemen have effected many other improvements in the manufacture.

Sheet-glass may be made of any thickness, and possesses considerable advantages over crown-glass from the greater size of sheets obtainable. For the Great Exhibition of 1851, cylinders were blown yielding sheets 49 by 30, which were cut into panes 49 by 10. Of these, 300,000 in number, and 400 tons in weight, were made in a few weeks, and without disturbing the ordinary economy of the manufactory in which this large order was executed. Sheet-glass, however, is wanting in the brilliancy of crown, and has on its surface 'cockles,' which refract and reflect the 'light in various and contrary directions; and the objects seen through the glass are thereby distorted.' Mr Shaw gives the following as his notion of the cause of this defect:—'When the divided cylinder is softened by heat, and either allowed to flatten by its own weight, or flattened by the workman, the concave interior of the cylinder has to expand, and the convex exterior to contract as the curved surface becomes plane. Were this contraction and expansion to take place uniformly throughout the glass, the undulation in question would not occur; but since one part invariably yields somewhat more readily than another, perfect flatness cannot be attained.' To remove this defect, was for long the desire of manufacturers; in France and Germany, the sheets were made of greater thickness than required, and ground down to flatness. The introduction of machinery for grinding and polishing by Mr James Chance of Messrs Chance and Co. of Birmingham, effected quite a revolution in the trade in this country, and is characterised as one of the 'greatest improvements which has ever been introduced in the manufacture of glass.' By this means, large sheets are obtained, in appearance equal to plate-glass, and at a price very little above that of the old form. In Mr Chance's plan, each sheet of glass is laid upon a flat surface, covered with damp leather—'the sheet adhering completely to the leather, after having been pressed against it, producing in truth a vacuum, which maintains the whole sheet in a flat position. Two sheets having been placed in this manner, each on a retaining or sucking surface, they are turned against the other in a horizontal position, sand and water being constantly supplied between them; and by means of the most ingenious machinery, the two surfaces rapidly rub one against the other in all directions, and are ground at the same time by the sand.' The other sides are then subjected to the same process. A very thin layer only of the surface is rubbed off, the sheet lying so perfectly flat.

Plate-glass.

The manufacture of plate-glass requires greater care than either of the two preceding kinds, and the process is different—the plate-glass being moulded, and not blown, as is the case with other kinds of glass-ware. Two kinds of crucibles are required in the manufacture of plate-glass—namely, the pots in which the materials are melted, and the basins from which it is poured upon the moulding-plate. These crucibles are made from a clay entirely free from iron and lime, and which is dried, ground, picked, washed in water, and passed through a fine hair-sieve. Old crucibles ground to a powder are mixed with the clay in proportions according to its quality. This composition, when prepared, is called *slip*, and is also used for cementing the furnaces.

The materials of which the glass is composed are first put into the pots to be fused, which occupies about sixteen hours, and then transferred to the basins. The transfer of the melted glass from the pots to the basins is called *lading*, and is performed by ladles of wrought iron, furnished with long handles. This second melting is called *refining;* and the glass is allowed to remain other sixteen hours, which is necessary for the disengagement of the air-bubbles introduced by the transferring, and for giving the metal the proper consistence for casting. For three hours previous to the casting, all the openings in the furnace are closed—an operation called *stopping the glass*, or *performing the ceremony*. The glass is tried; and if found of the proper consistence, and free from air-bubbles, the basins are carried to the casting-table. This is made of cast iron, and on it the melted glass is poured, and flattened or rolled out by passing a roller over it. After being inspected, it is put into the annealing-furnace, in which it remains for fifteen days. When properly tempered, the rough edges are cut off with a diamond, and the plate is now ready for grinding and polishing. This is, in all large establishments, performed by machinery, and by a process very similar to that already described for sheet-glass. The grinding first levels the surfaces; emery is next employed to smooth, and wooden blocks, covered with layers of woollen cloth, to polish them. Patent processes are now in operation by which plate-glass receives a peculiarly dazzling metallic lustre, and by which elaborate ornamental designs can be imparted to its surface.

Plate-glass is extensively manufactured into *mirrors*, which has hitherto been done by applying a layer of tinfoil, alloyed with mercury, to the posterior surface of the glass. Various improved processes are now, however, in use for effecting the 'silvering' of mirrors; among others, we may notice the method adopted by M. Tourasse, which is an improvement on that patented by Mr Drayton of Brighton. By this plan, mirrors may now be made in a very short time, and of any shape. A solution containing nitrate of silver and other ingredients is poured on the plate, when after a time a deposition of silver takes place on the surface of the glass. The liquid is then poured off, and the silver, when dry, is protected by a coating of bees' wax and tallow.

Flint-glass.

Flint-glass, or crystal, is composed of Lynn sand—which is calcined, sifted, and washed for the purpose—red-lead, or litharge, and refined pearl-ash. It was formerly made of calcined flint, but the finest Lynn sand has been found to produce a clearer ware, and is therefore preferred.

A flint-glass furnace varies little from those described for other kinds of glass, except that it is round in the top. The pots in which the glass is melted have their tops arched over, that no dust may fall in, with a hole at the side near the top, for the insertion of the tube. When the glass is sufficiently melted, the tube is inserted, and a quantity lifted out upon its point, in the same manner as for crown-glass. After being rolled upon the marver, the glass is blown out to a globe-shape, when the punty-rod is attached, and by means of an instrument resembling a pair of sugar-tongs, the glass is moulded to the form required. The shapes into which flint-glass is manufactured are so numerous, that it would be almost impossible to describe them all. The operations are extremely simple and beautiful, and are performed with a rapidity which is truly astonishing. The workman is furnished with a pair of compasses and a graduated scale, to measure the articles which he is making, by which they are kept of a uniform size. When finished, the articles are all weighed, to see that the right quantity of glass has been used in their manufacture, and after this they are put into the annealing-furnace.

Optical glasses are made from crystal, in which case the utmost care is necessary to keep the metal entirely free from waves, otherwise the glasses will be useless. An *achromatic* object-glass for a telescope or microscope—that is, an object-glass which does not produce coloured fringes around the edge of the image—distinguished as chromatic aberration—must consist of two lenses made of different kinds of glass, differing in the proportion

which their refractive bears to their dispersive power. Flint-glass and crown-glass are well adapted for being formed into such a compound lens, the dispersive power of the former being nearly double that of the latter, while the mean refractive powers of the two kinds are nearly the same.

Bottle-glass.

Bottle-glass is composed of the coarsest materials, generally soap-boilers' waste and sand. The furnaces for preparing bottle-glass are similar to those used for crown-glass; and the raw materials are treated much in the same way. As the mixture always contains a very small relative proportion of the alkaline ingredient, its vitrification requires a high temperature; but it is usually complete in eighteen or twenty hours. After the undissolved matter has subsided, the *sandiver*, or 'scum,' which rises being skimmed off, and the glass cooled down to blowing consistency, the mass may be worked up into bottles. For this purpose, the workman introduces his tube, and when sufficient is gathered upon the end, he rolls the glass upon a stone, blowing into it at the same time. He then puts the metal into a brass or iron mould of the shape of the bottle to be made, and blows through the tube until it comes to the desired form. This mould is so contrived as to open down the middle by means of a spring which the blower works with his foot. The mould is open when he puts in the metal at first; it is then immediately closed, and opened again when the bottle is formed, which is handed over to the finisher. The finisher detaches the tube from the mouth of the bottle, and fixes the punty-rod to the bottom. He then warms the bottle at the furnace, and takes out a small quantity of metal, which is turned round the upper part of the neck, and forms the rim usually seen on bottles. The finisher next employs a pair of shears to give the right shape to the neck: on one of the blades of the shears is a piece of brass resembling a cork, by which the inside of the neck is formed. The bottles thus finished are sent to the annealing-arch, which is kept a little below melting-heat until full, when the fire is allowed to die out.

Cutting—Grinding—Etching.

The instrument universally employed in *cutting* window-glass is the diamond, which is set into a metal socket, attached to a wooden handle for this purpose. The cutting point of the diamond must be a natural one; artificial points, as well as those produced by breaking the diamond, only scratch the glass, without producing the deep cut which is necessary.

What is called glass-cutting, or *grinding*, is a separate trade from blowing in all glass-manufactories. The cutting-wheel is driven by means of a belt proceeding from a large drum attached to an engine or other moving power. Above the cutting-wheel is a conical box, from which wet sand drops upon it, while another is placed below, to receive the sand as it falls from the wheel. The wheels used are three in number: the first is made of cast iron, by which the rough glass is ground; the second, of Yorkshire stone, by which the vessel is smoothed; and the third, of willow-wood, by which the final polish is communicated. For this latter purpose, the wooden wheel is dressed with rotten-stone or pumice-stone; and for imparting the highest degree of polish, putty powder is used. These wheels are of various forms, according to the shape of the vessel to be cut. They may be broad or narrow, flat-edged, two-edged, concave, convex, &c. The cutter holds the glass to the wheel while it is revolving, and the most beautiful and regular figures are engraved in this manner with astonishing rapidity. Imitations of cut-glass vessels are made by blowing the soft glass into a polished metallic mould, the form of which it acquires with as much faithfulness as wax.

As stated under CHEMISTRY, the vapour of hydrofluoric acid acts energetically on glass, and is sometimes employed for the purpose of *etching* on this material. 'The art,' says Parnell, 'may be practised on all kinds of glass, but the most proper description is good crown-glass. The facts on which the art is founded are, that glass becomes powerfully corroded by exposure to the acid in question, and that certain parts of the glass may be easily protected by a resist varnish, on which the acid exerts no action, except at a high temperature.' A variety of processes are now in use for decorating the surfaces of glass ware; space prevents us, however, from noticing any of these; we refer the reader, therefore, to other and larger works, for a description of them.

Staining—Colouring—Enamelling.

The art of staining or colouring glass is believed to be coeval with the discovery of the article itself. It is certain that it was known in Egypt several thousand years since, and tradition gives the honour of the discovery to an Egyptian king. The art of combining colours so as to produce pictures is of more recent date. The early specimens of stained glass exhibit a number of different pieces of various colours, joined together like mosaic work, so as to bring out the representation desired. This can now be done on one entire sheet. For a long period, the pictured glass used in cathedrals, &c., was merely painted on the surface, and was consequently liable to be rubbed off. The colours now are incorporated by fusion, and cannot be obliterated but by the destruction of the glass itself. The discovery of this art is ascribed to a painter in Marseilles, who went to Rome during the pontificate of Julius II. It was afterwards greatly improved by the celebrated Albert Durer and Lucas of Leyden.

All the pigments used in painting on or staining glass are oxides of metals or minerals—as gold, silver, cobalt, manganese, &c.—which, after being laid on, are subjected to a strong heat, until they penetrate into the body of the glass, or become fixed on its surface, and thus give out their fullest brilliancy and transparency. Animal and vegetable matters, which are freely used as colouring in ordinary painting, are wholly excluded in this, as the operation of the fire would entirely destroy their colouring properties. The colours that are meant to penetrate into the glass for the purpose of staining it, are wholly transparent, while those which are merely fixed upon the surface are only semi-transparent. Any colour or tint can be communicated to the glass in this way, and the art is at present practised with great success. The description of glass best adapted for painting upon or staining, is the finest crown or window-glass.

'The substances employed'—we quote from Parnell's Applied Chemistry—'for rendering colourless and some coloured glasses more or less opaque, like enamel, are phosphate of lime, fluor-spar, arsenious acid, peroxide of tin, phosphate of lead, and phosphate of antimony. Phosphate of lime, which is the only one of these materials commonly employed at present, with the exception of fluor-spar, is introduced in the form of finely powdered calcined bones, to the amount of one-twentieth to one-thirtieth of the weight of the glass. A very beautiful opaline crystal is obtained in this way.'

The applications of glass prepared and ornamented as above are almost innumerable. Its use for windows, mirrors, bottles, decanters, drinking-glasses, and other vessels of domestic utility; for optical lenses, and the construction of chemical and philosophical apparatus; for decorative mouldings, chandeliers, and articles for the boudoir; for beads, spangles, gems, and other personal ornaments—must be familiar to every British reader. Since the abolition of the duty in 1845, its use has been extended in horticulture and in the dairy, and in a great variety of ways; and it is not too much to predict its application, on a large scale, to other

economical purposes for which, by its beauty and durability, it is so eminently adapted.

PASTES—ARTIFICIAL GEMS.

In gem-sculpture, *paste* is the term for a preparation of glass, calcined crystal, oxide of lead, and other ingredients for imitating gems. This art appears to have been well known to the ancients, and after being lost, was restored, at the end of the fifteenth century, by a Milanese painter. The general base of artificial gems is a vitreous compound known as the 'Mayence base' or Strass (from the name of its inventor). It is prepared, according to Fontanieu, in the following manner:—8 ounces of pure rock-crystal, or flint, in powder, mixed with 24 ounces of salt of tartar, are to be baked, and left to cool. The mixture is to be afterwards poured into a basin of hot water, and treated with dilute nitric acid till it ceases to effervesce; and then the frett is to be washed till the water comes off tasteless. This is to be dried, and mixed with 12 ounces of fine white-lead, and the mixture is to be levigated and elutriated with a little distilled water. An ounce of calcined borax being added to about 12 ounces of the preceding mixture in a dry state, the whole is to be rubbed together in a porcelain mortar, melted in a clean crucible, and poured out into cold water. This vitreous matter must be dried, and melted a second and a third time, always in a new crucible, and after each melting, poured into cold water, as at first—taking care to separate the lead that may be revived. To the third frett, ground to powder, 5 drachms of nitre are to be added; and the mixture being melted for the last time, a mass of crystal will be found in the crucible of a beautiful lustre.

A base being thus prepared, the peculiar colours are obtained from the metallic oxides, which, in proper proportions, under the hands of an experienced manipulator, are said to yield imitations so like the natural gems, that none but lapidaries or mineralogists could detect the deception. In general, the artificial products are softer, more readily scratched, and of less specific gravity than the real gems; while their power of refracting light is also different—a test that can be applied without unsetting them.

CEMENTS—ARTIFICIAL STONES.

Under this section we rank those compositions generally known as cements, mortars, concretes, plasters, and stuccoes. Their preparation, for the most part, involves a knowledge of chemical principles, and their practical application as ornamental mouldings, substitutes for sculpture, and the like, is an art as strictly fictile as the fabrication of earthenware or porcelain.

The *mortar* or cement employed to unite stones and bricks into a compact mass in building, is composed of quicklime, sand, and water. Quicklime is procured by roasting or calcining limestone in kilns, into which moderate-sized fragments of the rock are placed in alternate layers with coal or turf. By this process, water and carbonic acid are expelled, and the limestone converted into what is called *shell* or unslaked lime. The shells are then reduced to powdery quicklime by *slaking*—that is, by pouring as much water upon them as will suffice to destroy the cohesion of their particles. When intended for mortar, the quicklime should be immediately incorporated with sand, and used without delay, before it imbibes carbonic acid from the atmosphere. Lime, thus mixed with sand, becomes harder, and more cohesive and durable, than if it were used alone. The cement formed in this manner continues to increase in strength and solidity for an indefinite period, partly from the hydrate of lime being gradually converted into a carbonate partially crystallised, and partly from the formation of silicates.

When common mortar is made so fluid with water as to be poured on a course of brick or stone work, it is known by the name of *grout*. Where great strength and durability are required, the practice of grouting the hearting or packing of the walls is usually adopted; as by this means the interstices are filled, and the whole rendered, by the hardening of the lime, a solid compact mass. Foundation *concretes* are generally formed of small angular stones well packed and grouted. Such concretes are proof against all moisture and decay, and, on indifferent subsoils, form more resistant foundations than isolated blocks of stone, however large and heavy.

Hydraulic or *water cements*, also called *Roman cements*, are those which have the property of hardening under water, and of consolidating almost immediately on being mixed. Common mortar, although it stands the effect of water very well when perfectly dry, yet occupies a considerable time in becoming so, and dissolves or crumbles away if laid under water before it has had time to harden.

A great variety of artificial hydraulic cements are now in use, the best known of which we may here shortly describe. 1. *Portland Cement*.—This important cement is 'made from carbonate of lime, mixed in definite proportions with the argillaceous deposit of some rivers running over clay and chalk, pounded together under water, and afterwards dried and burned. The strength of the composition is very remarkable, being nearly four times as great as that of any other kind. Portland cement makes an admirable and most powerful concrete, the proportion of cement required being only a tenth or a twelfth part.' 2. *Parker's Cement*, known otherwise as compo, is much used for facing houses, water-cisterns, setting the foundations of large edifices, and the like, and is described as follows in the *Engineers' Journal*:—This valuable cement is made of the nodules of indurated and slightly ferruginous marl, called by mineralogists *septaria*, and also of some other species of argillaceous limestone. These are burnt in conical kilns, with pit-coal, in a similar way to other limestones, care being taken to avoid the use of too much heat, as, if the pieces undergo the slightest degree of fusion, even on the surface, they will be unfit to form the cement. After being properly roasted, the calx is reduced to a very fine powder by grinding, and immediately packed in barrels, to keep it from the air and moisture. For use, it is tempered with water to a proper consistence, and applied at once, as it soon hardens, and will not bear being again softened down with water. 3. *Atkinson's Cement* is made from the lias rock. Natural substances are also frequently used for the formation of hydraulic cement. Of these, *puzzolana* is the most notable. This was used by the Romans in building the foundations of their quays, artificial islands, &c. It was discovered at Puteoli, the modern Puzzuoli, near Naples, from which it is now chiefly obtained. This earth is a light, porous, friable mineral, various in colour, and evidently of volcanic origin; mineralogically, it may be designated a calcined ferruginous clay. When reduced to powder by beating and sifting, and thoroughly mixed with lime, either with or without sand, it forms a mass of great tenacity, which in a short time cements to a stony hardness, not only in the air, but likewise when wholly immersed in water. To give the composition greater tenacity, it is occasionally mixed with bullocks' blood and oil. *Dutch trass* is a somewhat similar substance, which used formerly to be imported from Holland, where it is extensively used in hydraulic works. It is made from a light vesicular lava found near Andernach, on the Rhine.

Plaster, or the material which is used to spread smoothly over walls, is of various kinds. That which is applied to inner walls or partitions, is formed of certain proportions of slaked lime, fine sand, and water, with mixture of cow-hair, to assist in giving cohesion. The best plaster is now prepared by the pug-mill, by which the ingredients are more thoroughly incorporated

than by the old process of hand-beating. Spanish white, ochre, and other colouring matters are added when any peculiar tint is wanted; but we may here remark, that the most durable of all plasters, and that which answers best even for fresco-painting, is composed simply of well-slaked lime and sifted river-sand. The surface of plaster is now seldom finished with a view to permanent exposure—whitewashing, sizing in colours, oil-painting, and, above all, papering being the prevalent fashions of the day.

Stucco is the name ordinarily given to plaster of Paris, which is gypsum reduced to a powder by heat and grinding; but the term *stuccoes* is further extended to embrace all those compositions with which walls are coated or ornamented, in imitation of stone. Gypsum, which is found in roundish hard masses, is properly a sulphate of lime; and, like all other varieties of lime, it has a strong power of absorbing water. The practice is, to put the masses into a heated oven, and when duly baked, to take them out, and grind them to powder in a mill. This powder, when sifted, is a beautiful white substance, resembling flour. A quantity of powder being put in a vessel, water is poured upon it, and immediately the stuff thickens in a surprising manner, and becomes a hardened mass. While still thickening or setting, it is poured into a mould for any required shape; or it may be applied along with a little lime as a fine plaster, which it is desirable should dry speedily. It is used largely for all kinds of casts from pieces of sculpture, mouldings for cornices, and for stereotyping. There are none of the artificial stuccoes which yield so sharp or delicate a cast; but most of them excel it in hardness and durability. Gypsum, or sulphate of lime, is the basis of all the cements known as Keene's, Martin's, Parian, &c. In these, the 'plaster in the state of fine powder is thrown into a vessel containing a saturated solution of alum, sulphate of potash, or borax. After soaking for some hours, it is removed, and air-dried, and subsequently rebaked at a brownish red heat.' It is finally reduced to a fine powder, which, when required for use, is mixed with a solution of alum. 'When borax is used, the plaster is called *Parian*, but where sulphate of potash is employed, it forms Keene's Cement. The kind called Martin's Cement is made with pearl-ash as well as alum, and is baked at a much higher heat than the rest.' All these cements are greatly used, and are particularly valuable 'when a hard durable substance is required, uninjured by damp, and perfectly safe from the attacks of vermin.' They are worked with great facility.

Scagliola is the Italian term for a composition intended to represent various marbles, porphyries, serpentines, &c. It is composed of fine plaster of Paris, with colouring matters, cemented by glue or isinglass, and is sometimes studded with chips of alabaster, &c., to imitate verd-antique. It is laid on like common stucco, moulded into the desired forms, and allowed to set. When thoroughly set, it is smoothed with pumice-stone, and washed; then polished with tripoli and charcoal; next with tripoli and oil; and finally with pure oil, laid on with cotton wool. The result is a surface of unusual richness; but from the nature of the ingredients, it is only fitted for internal decoration, and even then requires to be kept dry.

The material known as 'metallic lava' is a patented composition, capable of being moulded into forms of great variety; it is also well adapted for pavement in which mosaic work can be imitated.

Bituminous Cement.—This is best known by the name of Asphalte. Asphalte, or asphaltum, is a bituminous mineral, allied in its nature to pitch, and is found in the form of rocky masses in different parts of the world. For pavement, it must be mixed with sifted gravel, pounded iron slag, or river-sand, which gives it more stability, and a degree of roughness that is not unnecessary. The composition is prepared in portable boilers or caldrons, and spread while hot on a properly prepared bed; and being rendered smooth on the surface, it offers an exceedingly agreeable resistance to the foot, being not so hard as stone, nor so soft as a mud pathway. Wherever stone is expensive, asphaltic pavement may be advantageously employed, not only for streets, but floors of dairies and other outhouses, garden-walks, and terraces.

Mastic is properly a resinous substance obtained from incisions made in the branches of the *Pistacia lentiscus*, and received its European name from being chewed or used as a *masticatory* by women in Turkey, for the purpose of cleansing the teeth, and imparting an agreeable odour to the breath. But the term *mastic* is also applied —not very appropriately—to certain cements which are used for architectural decoration, and which it is not necessary here to describe.

Various *artificial stones*, besides those for ornamental purposes, have recently been brought under the notice of the scientific. From the attention bestowed on their production by practical men, and the best of them having for their object the utilisation of products now considered as refuse, there is every probability of the manufacture becoming an important branch of social industry. Before noticing these artificial stones, we shall glance at two methods of imitating the endless varieties of marble. The most celebrated of these is Magnus's enamelled slate. This material, from its comparative cheapness, its great strength, lightness, and the ease with which it can be worked into an endless variety of forms, is exceedingly well adapted for household and decorative purposes. And now that the method of imitating, through its means, the finer varieties of marble has been successfully established, its use will doubtless be greatly extended. The exact nature of the process has not been made public; but after the colouring is laid on, the slate is subjected to a temperature of from 310° to 500° for several days. By this means, the colours are rendered very permanent. Messrs Iles & Co. have invented an ingenious and cheap method of imitating marbles in hard and soft cement. The effect is produced by the waste materials of silk-works, or the short cuttings from piled fabrics, as cloth and velvet, mixed with the cement; the whole thus forming a mass having either a uniform colour or a mixture of colours throughout; while the veins are formed by silk threads drawn out to imitate such appearances as may be fancied. A great advantage in point of cheapness is thus obtained, and in some cases a polish can be produced during the laying on of the cement. The price per foot is 4½d. for hard cement, while that of scagliola of the plainest description is 6s. 6d., the durability of the one being quite as great as the other. We now proceed to notice the varieties of artificial stone which have taken a place as of recognised utility.

The first in point of date is the 'patent stone' of Messrs Ransome and Parsons of Ipswich. A soluble glass is first formed by boiling flints in caustic soda under pressure; this liquid cement is then ground up with equal parts of pipe-clay and powdered flint, and the whole intimately mixed with ten parts of sand. The putty-like substance thus obtained is moulded into any shape required, slowly air-dried, and finally kiln-burned at a bright-red heat. During the firing, an insoluble glass is formed, by the soda taking up more silica and alumina.

Although easily adapted to a variety of purposes, one objection to the use of this stone, is the efflorescence which in process of time disfigures the surface. One purpose for which it has been found to answer admirably, is the formation of porous filter-stones, which are supplied at a cheap cost. Scythe and grind stones have also been made of it.

We next notice the process of M. Kuhlman, which, according to the editor of the well-known continental scientific journal *Cosmos*, is 'likely to tend to the

production of a great and new industry.' The attention of M. Kuhlman has for some years been directed to the constituents of lime cements. An examination of these led him to believe that all limes, more particularly hydraulic limes and natural cements, contained quantities of potash and soda—the part which these substances played in stones and cements being, that they 'served to bring the silica to the lime, and thus to form silicates, which, by means of the application of water, solidified a portion of the mass, producing the formation of a hydrate analogous to that which takes place with plaster.' A variety of experiments enabled M. Kuhlman to produce with fat limes and a silicate of potash—10 or 12 of the latter to 100 of the former, the whole very well pulverised and mixed—limes possessing all the characteristics of hydraulic limes. Noticing thus the affinity of lime for silica dissolved in potash, M. Kühlman was led to direct his attention to its action on calcareous stones. Here the success of his experiments opened up a very wide and important field; namely, the conversion of masses of soft limestone or chalk into hard durable stone, susceptible of a high polish. 'Chalk, whether in an artificial paste, or in its natural state, plunged into a solution of silicate of potash, takes up, even when cold, a quantity of silica, which may be increased considerably by exposing the chalk alternately to the action of the silicious solution and the air. The chalk assumes a smooth appearance, a compact grain, and a colour more or less yellow, according as it is more or less impregnated with iron. The hardness, which is at first but superficial, penetrates by degrees into the centre, even where there is considerable thickness.' To harmonise the shades, the inventor uses with a very white chalk 'a double silicate of potash and magnesia. This is a vitreous substance which forms a brown solution, and which, when used in the process, causes a little oxide of manganese to be deposited in the artificial silicious paste.' Where ferruginous limestone is used, the too sombre shades are harmonised by using in the silicate solution a small quantity of 'artificial sulphate of barytes, which, in penetrating the porous stone, whilst it forms a layer of silica, remains fixed, entering into a state of chemical combination.' M. Kuhlman's researches into the harmonising of the shades of the blocks of stone thus obtained, led him to the discovery of the means of giving an almost endless variety of tints and shades to their surfaces. This he effects by the use of metallic sulphates. Thus, sulphate of copper gives a beautiful green tint; sulphate of manganese, a brown. From the cheapness of the material, and the ease with which it can be worked into a vast variety of shapes, 'this method of converting soft lime into silicious limestone is likely to become a great acquisition in the art of building.'

If there is one feature which distinguishes the practical science of the present day more than another, it is the endeavours, many of them eminently successful, which it makes to convert the waste or refuse results of one manufacture into the useful and valuable products of another. To the utilisation of one refuse product, which is produced in vast quantities, and, being difficult to be got rid of, at present entails a burden upon the manufacture, practical men are now directing their attention, and with every prospect of success. We refer to the 'slag,' as it is termed, or the molten mineral products of our iron-smelting furnaces. Some idea of the quantity available of this material may be obtained, when we state that for every ton of iron produced two tons of slag result; and that three millions of tons of iron are produced in this country yearly. To this must be added the slag resulting from other metalliferous manufactures. This slag has hitherto had no commercial value; on the contrary, ironmasters have to get rid of it at an extra cost, varying from 9d. to as much as 3s. 6d. per ton. One authority calculates that in this way are lost at least £150,000 yearly, not taking into account the loss of the material itself. What this loss is, may be estimated from what Dr Smith, the patentee of a new process for utilising the material, says of its commercial capabilities: 'In the utilisation of slag by the processes of refining, casting, pressing, rolling, moulding, and annealing, we can avail ourselves of the facilities afforded by the extremely liquid state to which the slag is reduced in the smelting-furnace, so that we have only to prepare suitable appliances to be able to impart to it any desired form, colour, or texture. According to the treatment which it receives, slag can be rendered brittle or tough, hard or soft, compact or porous, rough or smooth. It can be cast into as great a variety of forms, solid and hollow, as iron itself, with the superior advantage of being susceptible of the admixture and blendings of colour, so as to render it equal in brilliancy to agate, jasper, malachite, the variegated marbles, and other more valuable varieties of the mineral kingdom. When properly annealed, it can be made to acquire a surface or texture at least ten times as durable as that of marble, and is susceptible of a polish equal to agate or cornelian.' From all that we have learned of this material, the above description of its properties is by no means overdrawn.

Slag has long been used on a small scale for a variety of purposes, the material being simply withdrawn from the smelting-furnace, and cast into the desired form, without any other process. The patent of Dr Smith, which is now the property, we believe, of a public company, who intend introducing the material on a large scale, has reference to the refining of it to such a degree, that a high commercial value is given to it. The main features of the process consist in 'the use of *pure* slag in its most favourable molten condition—protecting it from all admixture of foreign ingredients or débris; carefully refining it, so as to secure a uniform homogeneous product; and subsequently, by appropriate machinery, casting, stamping, pressing, cutting, rolling, &c.' The process of annealing is a most important one, and requires to be performed with the greatest care.

The patent process of Nesbet and Elliott for the utilisation of slag is, compared with that above described, very simple, the slag being merely moulded on iron plates, and then annealed. Paving-flags made on this principle were put down in Paris some years ago, and are still in use. Experiments as to its resistance to crushing powers, shew that this material has a very high value. While the process of Dr Smith has more especial reference to the production of ornamental articles, that patented by Mr Elliott takes up the manufacture of articles of utility chiefly, as bricks, tiles, draining and sewage pipes, &c., for which, with due care in annealing, this material seems admirably adapted, from its 'absence of porosity and impossibility of decomposition.' It is not a little remarkable that, in consequence of the difficulty met with in persuading ironmasters to use the slag which is positively a loss and a nuisance to them, Mr Elliott in his later patents has been forced to use an artificial slag, which is obtained by the fusion of the common brick-earths, these containing all the elements of slag—as lime, silica, and alumina. For this purpose, reverberatory furnaces are employed, the waste heat from which is used for a variety of other purposes.

A species of artificial stone, invented by the Messrs Chance of Birmingham, is obtained by the fusion of the Rowley ragg or basaltic rock of Dudley. By annealing, this returns to the basaltic condition; and by rolling, remains vitreous like glass. It is applicable to decorative and constructive purposes, and is very cheaply made.

The subject of the production of artificial stone is of vast commercial and social importance, and now that this is recognised by practical men, we have no doubt that the difficulties attendant upon the various processes will be gradually overcome.

Moulding compositions for making architectural

ornaments in relief are now extremely common, and in most instances well fitted for the object in view. The substances chiefly used for this purpose are carton-pierre, papier-mâché, stamped leather, and gutta-percha. Carton-pierre is now very largely used. From its lightness, durability, and ease of application, it is peculiarly adapted for architectural decoration. It is composed of 'the pulp of paper mixed with whiting and glue. This preparation is pressed into plaster piece-moulds, backed with paper, and then, when sufficiently set, removed to a drying-room to harden.' The drying is effected in a few hours, which is a great advantage. When papier-mâché is used for relief ornamentation, its preparation differs slightly from that of the material when employed to make trays and other similar objects. Sheets of brown paper are glued together, and pressed into a metal mould, which gives the form required. This is removed, and trimmed up. A pulp of paper and resin and glue is then put into the mould, and the ornament again pressed into it, which takes up the pulp, &c., and gives a sharpness of outline. Stamped leather is now becoming much used for relief ornament. The leather, properly prepared, is stamped with the ornament through the aid of a hydraulic-press, which gives a high and sharp outline. The hollows in the back are then filled up with a composition, which prevents the ornament from subsiding.

Caoutchouc and *gutta-percha*, two remarkable substances of vegetable origin—to be afterwards treated at length—can scarcely be omitted in any account of modern fictile fabrics. The former, being highly elastic, reducible by heat, soluble only in certain liquids, and capable of chemically uniting with several substances, is applicable to a thousand purposes of utility and ornament. The same remark may be applied with equal propriety to gutta-percha, which is also soluble only in certain liquids, is reducible by heat, and though inelastic, is much more ductile and plastic than caoutchouc. In our textile fabrics, both now occupy a prominent part; while, as fictile materials, they may be formed into ligatures and belts, tubes, bottles, springs, boots and shoes, water-proof vessels, knobs and handles, ornamental mouldings, and used as ingredients in pavements and floorings of a very durable kind.

The most recent improvement in the caoutchouc or India-rubber manufacture is treating it with coal-gas tar. The product possesses some very remarkable properties, rendering it, amongst other things, easily moulded into a variety of shapes, possessing great strength. It is proposed to apply it even to the production of articles of furniture, for which it seems well adapted.

Decorative Design as applied to Fictile Manufactures.—In the application of decoration to our various manufactured articles, there is a great diversity of opinion as to what constitutes correct canons or rules of taste. To give even the briefest résumé of the various opinions, would occupy a far greater space than we can afford; we must therefore content ourselves with noticing the general principles which few are found to dissent from.

The primary design of every manufactured article is to serve some purpose of utility. The article may have no other characteristic whatever save that naturally belonging to the material and the form given to it, to serve the use to which it is to be put. But to please the eye and gratify the taste of the owner, other characteristics may be given to it; and these may be derived from an adaptation of the ever pleasing and graceful forms of nature, or of those conventional forms which have been used by ancient nations in the decoration of their edifices. This desire to ornament those things which surround us —the house which shelters, the clothes which cover us, and the household utensils we use—has been a characteristic of man in all stages of his civilisation; so much so, that it seems to be a natural want. In early times, the shepherd in his silvan hut might festoon its interior with graceful trails of the vine-leaf, and twine a wreath of flowers round the gourd out of which he refreshed himself from the crystal spring. The savage of the present day, in the isles of the sunny south, struts about with a piece of gaudy cotton print, with as much satisfaction as the London lady derives from her flaunting brocade. It is, then, of some importance—at least in a commercial sense—that this love of ornamentation, which we find so universally diffused, should be encouraged; and it is of great importance, in an æsthetic or artistic sense, that ornament or decoration should be carried out in conformity with principles calculated to promote correct taste, and to throw around even the most common article the grace of beauty and true elegance.

We have said that utility is the primary design of all manufactured articles; this, therefore, should never be lost sight of, but the ornament should always be subservient to the main design. Ornament has therefore been defined as the 'decoration of a thing constructed.' Thus a jug is designed to hold a fluid, and to allow of it being taken from and put into it with great ease; but if the form, or the ornament added to the form, be of such a kind that the jug cannot be used as a jug, it is merely an ornament having the shape of a jug. When we find articles, such as vases, having forms or ornament given to them entirely inconsistent with their known uses, we at once trace a want of truth in the design. From these considerations is derived the canon or rule, that 'ornament should arise out of, and be subservient to construction.' It is in this sense that architecture has been defined as 'decorated construction.'

The next point to be noticed is the *material* of which the manufactured article is composed. As each material has its characteristic peculiarity, which is inseparable from it, the design should be subservient to and aid in bringing out the characteristics of the material. 'The treatment and feeling,' it has been truly remarked, 'of true works of art must, and ought to take their tone from the materials employed.' Thus, iron and glass at once convey each a certain constructive peculiarity to the mind; and where we see an article of iron and one of glass having both the same peculiarities of design, we feel at once that an inconsistency has been perpetrated, and that both cannot be right. Again, silk has a certain distinctive character, and cotton another: to decorate both, therefore, in the same way would be wrong; one of the objects would of necessity be characterised by a want of truth. Hence is derived the canon, that 'ornament requires a specific adaptation to the material in which it is to be wrought, or to which it is to be applied.'

Ornament is derived from three sources: from natural forms, from the conventional scrolls used in the decoration of ancient architecture, and from simple geometrical figures. These, of course, are all resolvable into one source—that of nature; but it is convenient to arrange them as above. There are two great schools of ornamentists. One school hold that natural forms closely imitated are the best suited to the decoration of works of utility or art—that, in the words of one of its most eloquent followers, 'all the true nobleness of art had come from people loving nature in some way or the other, expressing their sentiments about nature; and exactly in proportion as the reference to nature had become *more direct*, the art became nobler.' The other school hold widely different views. Thus one of its ablest exponents gives the following:—'Flowers or other natural objects should not be used as ornament, but *conventional* representations founded upon them, sufficiently suggestive to convey the intended image to the mind, without destroying the unity of the object they are employed to decorate.' The government 'Department of Science and Art' takes this view, for one of the principles of decorative art published under its sanction is the following:—'True ornament does not

consist in the mere imitation of natural objects, but rather in the adaptation of their peculiar beauties of form or colour to decorative purposes, controlled by the nature of the material to be decorated, the laws of art, and necessities of manufacture.' To take up space in investigating which of the two schools, the 'natural' or the 'conventional,' is the correct one, would serve no useful end; at the same time, we may say that the middle course seems the best. There are certain natural forms which, applied to certain purposes, would be best adapted the more closely they were imitated; while for other purposes, a conventionalising would be in better taste. Everything depends upon the material to be ornamented, the way in which this material is to be manufactured, and the uses to which the manufactured article is to be put. It is manifestly erroneous to apply a close imitation of a natural form to an article the use of which conveys an idea altogether opposed to that which the natural form suggests. Thus when we see a gas jet issuing from a water-lily, or water-plants spread over the surface of a carpet, we are at once struck with the obvious inconsistency. But referring the reader to special works on design for further information on the points we have indicated, we shall proceed to offer a few remarks on the application of decorative design to the various fictile manufactures which form the subject of the present paper. Taking these in their order as we discussed them, our remarks will first have reference to ceramic manufactures—pottery and porcelain.

The first point to be attended to is utility. To give a form, for instance, to a vessel which prevents its being cleaned, or to put a handle to it in such a way as to prevent it being lifted, is a manifest absurdity; such absurdities, nevertheless, have been often perpetrated. The ornament should also be subservient to the purpose for which the vessel is used. Thus, where it is likely to be in frequent use, all ornament should be avoided which will render it difficult to be cleansed, or afford facilities for dust and dirt harbouring. The nature of the material will also dictate rules for its ornamentation. Thus brittleness will prevent ornament in high relief from being used: 'All projecting parts should have careful consideration, to render them as little liable to injury as is consistent with their purpose.' Again, the peculiar characteristics of the material should be preserved and brought out; hence the absurdity of applying a surface-colour which gives the idea of another material, as the metallic lustre we see often in common vessels, or one conveying the idea that the material is marble. 'Landscapes and pictures are almost always,' says Mr Redgrave, 'out of place in pottery; and it certainly is objectionable to cover the centres of plates and dishes with pictures and views, not only because it hides the surface which it has been before said it is desirable to retain, but because utility would be better served by the absence of any decoration on the part which receives the viands, to satisfy that sense of cleanliness only to be obtained by the white unchanged surface of the material. . . . . In the application of colour to porcelain and earthenware, the surface should never be wholly or indeed largely covered; the material has a purity that should be decorated, not obscured.'

In designing articles made of glass, due attention should be paid to the peculiar nature of the substance. Its transparency; its purity of surface, which, if tarnished by use, is easily restored by cleaning; its brittleness, which prevents its use for merely constructive purposes, as, for instance, where a weight is to be supported: all these should be considered in the design. The use to which the vessel is to be put, must also be considered. Our remarks on this point, in speaking of pottery articles, are applicable here as well. A great deal of bad taste is often displayed in ornamented glass. Its transparency is frequently marred by a redundancy of obscuration, effected by grinding, or it is rendered opaque by dead colouring, or imitations of other materials, as opal or metal. Its purity of surface is destroyed by an excess in cutting; and its absence of all constructive qualities forgot in its frequent adaptation to architectural decoration. On this latter point Mr Wallis very justly remarks: 'The inappropriateness of architectural details, the value of which as ornaments consists in their outline, and the effects resulting from a play of light and shadow, being applied *to*, and *in* a material in which the effects are obtained by a light in transition, is at once obvious, if that very simple but much neglected question as to the nature of the material to be used is even fairly asked and honourably answered.'

In the application of glass to *mere ornament*—meaning by this, articles not of everyday utility, as chimney-piece and drawing-room decorations—the peculiarities of the material are still more frequently ignored. Thus, colouring in rich tints, overlaying the surface with gilding, imitation of opal, papier-mâché, and porcelain, completely hide the peculiarities, and attach ideas to the material altogether wanting in truth.

As regards the form of the articles, that is the best which gives the idea of lightness and elegance. 'In all cases, elegance of form should be the first consideration, to which cutting, gilding, or engraving should be entirely subordinate.' The ornament, says another authority, should be 'so arranged as to enhance by its lines the symmetry of the original form, and assist its constructive strength.'

In the department of stained-glass decoration, much might be said, did space admit. There are two schools or modes of treatment—one, the oldest, in which the subjects were not treated pictorially, but composed with 'extreme monumental simplicity,' severe outline, and thoroughly flat treatment; the modern or continental school, in which all the characteristics of a picture, careful drawing and perspective effects, are attempted to be given. Each of these schools has its able advocates. Mr Ruskin's dictum is as follows:—It should 'always be remembered by the workman, that the use of a window was to let in light, and that the virtue of the glass in a window was to be transparent; and that all art which tried to represent it as opaque, as a picture instead of a window, was mistaken and absurd.'

Of the moulding compositions we have noticed, papier-mâché is the most generally used. As regards the received ornamentation of this material, Mr Redgrave says it is 'the most gaudily decorated of all manufactures, and seems quite beyond the pale of any just principles of ornament. . . . . At present, it is a mass of barbarous splendour that offends the eye, and quarrels with every kind of manufacture with which it comes in contact.' Many of our remarks in the next number will be found applicable to this material.

In drawing up the remarks in this and the following number on decorative design, as applied to manufactures, we have been much indebted, amongst other authorities, to Mr Redgrave, R.A., who has appended to the Jury Report of the Great Exhibition, a Report on Design, replete with instruction and suggestions of a highly valuable nature.

TEXTILE MANUFACTURES.

By *Textile Manufactures*—as generally defined—are meant those in which filaments of flax, of cotton, of silk, or of wool, are wrought into linen, cambric, calico, muslin, silk, satin, flannel, broadcloth, and the numerous modifications of these now so well known to every British reader. In the present instance, we extend the definition so as to embrace every variety of fabric—as paper, felt, straw-plait, and the like—essentially composed of vegetable or animal fibre. In the preparation of these, from the rearing of the raw materials to their ultimate stage as articles of utility and luxury, there is involved a vast amount of labour, of mechanical and chemical skill, of capital and enterprise—so much so, that, as a class, they rank second to none of the manufactures which come within the scope of our national industry. In the following pages, we aim at a very general account, seeing that complete details of any particular process would be not only inconsistent with our limits, but unintelligible without the aid of numerous diagrams, and also a certain amount of practical acquaintance with the subject under review.

LINEN.

Of the various textile manufactures, strictly so called, that of linen is the most ancient. In the oldest records of history, sacred and profane, mention is made of it; and the notices given of the fineness of its texture, are evidence of the degree of skill then displayed in its manufacture. The word *linen* is derived from the old name of the plant now called flax, which is preserved in *line*-seed, or *lin*-seed. Linen is cloth made of *lint* (Lat. *linteum*), which is the fibrous bark of the flax plant (*linum usitatissimum*).

The plant, which grows in temperate climates, and usually attains a height of from three to four feet, is an annual, having a slender, smooth, hollow stem, rising undivided till within a few inches of its full height; its several branches are then terminated by small blue flowers, to which succeed roundish seed-vessels, each enclosing ten smooth shining seeds, replete with meal and oily matter. As a crop, flax is cultivated less or more in most European countries, and succeeds best in a rich deep loam, with a good deal of moisture. That produced in Holland and Belgium is said to be best; but our chief supplies are obtained from Russia, Prussia, and other countries bordering the Baltic. Egypt, anciently so celebrated for its fine linen, is beginning to yield a portion of our supply, and promises well for the future.

From the cheapness of foreign flax, but chiefly on account of our farmers being prejudiced against it as an exhausting crop, its cultivation has been little adopted in Great Britain. In consequence, however, of the dissemination of practical information on points connected with improved culture, and the exertions of our agricultural societies, this prejudice against the flax-crop is fast disappearing, and its cultivation is taking the place in our agricultural operations to which its importance well entitles it. The soil found to be best adapted to the cultivation of flax is a sound, dry, deep loam, with a clay subsoil; draining and subsoiling of the land are important. The great point in the preparation of the land is to have it clean and free from weed, so that the root can penetrate the soil. The seed is sown broad-cast, and finished with the harrow and roller. The crop will be so much the more valuable if it is carefully weeded, as done in Belgium.

When the seeds are beginning to change from a green to a pale brown, is the best time for pulling the flax. Where the crop grows of different lengths, these lengths should be pulled and kept separately, uniformity in this respect being of great value in the after processes.

The process first gone through after pulling is *rippling*—which consists in pulling the stalks through a series of iron teeth eighteen inches long, placed within a distance of half an inch of each other. These are fastened in a block of wood, which is placed at the end of a plank or long stool on which the operator sits. The rippling deprives the flax of its seed-capsules, which, when thrashed, yield linseed, valuable as affording oil, and a refuse used for feeding cattle.

The next process is to obtain the flaxen fibre or lint free from the woody core, or *boon*, of the stem. This is effected by steeping the bundles in water till the boon begins to rot, in which state it is readily separated from the fibre. The operation is called rotting, or *retting*, and requires to be managed with great care, as by continuing it too long, decomposition might extend to the fibre, and render it useless; while by discontinuing it too soon, the separation could not be effected with sufficient ease. The time is generally determined by the nature and temperature of the water, and the ripeness of the flax—decomposition taking place more rapidly in soft stagnant water than in running streams, in which the retting is sometimes conducted. After being sufficiently steeped, the flax is spread out on the grass, to rectify any defect in the retting, and ultimately to dry it for the breaking. In some districts, it is the practice to conduct the retting entirely on the grass—a process known as dew-retting, in contradistinction to water-retting. This is a safer and less offensive method, but it requires much longer time, and in a country where land is valuable, would become very expensive. On the whole, the mixed method of retting is preferable—that is, to steep till decomposition of the boon is well advanced, and then to complete the process on the grass. It has been attempted to separate the fibre by machinery, without subjecting the flax to retting; but the article so produced has hitherto been rejected as inferior in quality.

To avoid the delays and uncertainty dependent upon the old processes of retting or watering, plans have been recently introduced, bringing the operation more under control, like the other processes of our manufactures. The methods which have been adopted, and are now working with success, are known as Schenk's and Watt's. By the first of these, the flax is placed in vats, in which it is kept down by means of strong framework. Water is allowed to pass into the vats, to become absorbed by the flax; steam is next admitted, till the temperature of the water is raised to, and maintained at, about 90°. Acetous fermentation ensues in a few hours; and after being maintained for about sixty hours, the decomposition of the gummy or resinous matter in the stalk is completed. The mucilage water is next withdrawn from the vat, and the flax taken out, separated and dried either in the open air or in desiccating rooms, according to circumstances. In Watt's process, the flax is placed in a chamber provided with a perforated false bottom; the top is double, and filled with water to act as a condenser. Steam being admitted to the case, the first result is the freeing of the flax from certain volatile oils. The steam, rising to the top of the chamber, is condensed by contact with it, and falls in showers on the flax beneath—a decoction of the extracted matter is thus obtained. In thirty-six

hours, the process is completed, and the flax, taken out, is passed between rollers in the direction of its length, which presses out the water and decomposed gum, and splits and flattens the straw. By this process, all that the plant takes from the land is saved—the seeds, the chaff, and the refuse water being available as food for animals.

Prepared by either of the plans, the flax is now ready to be freed completely of its woody particles. This is effected by *scutching*. Previous to this, however, the flax is passed through a *brake* or revolving rollers, in order thoroughly to crack the boon. The brake, worked by manual labour, consists of a frame, in the upper side of which are a number of grooves; a movable piece is hinged at one end, and provided with a similar grooved piece on its lower side, but so placed that the projections pass into the hollows of the lower. The flax, placed between these, and struck by bringing down the hinged part, is broken, but the fibre remains uninjured.

In the flax-breaking machine, the flax is passed through a series of horizontal fluted rollers; the flutes do not touch, thus preserving the fibre while breaking the boon. In Plummer's machine, five rollers are used, and the pressure on the flax is regulated by weights suspended to the axles of the rollers. Fig. 1 is a diagram illustrative of this machine; the flax to be broken is laid upon the table *f*, and passed between the rollers *a*, *b*; from these it is led by the curved plate *hh*, to the rollers *b*, *c*; from thence to *d*, *e*, and finally placed on the table *g*.

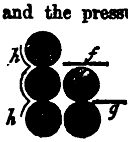

Fig. 1.

In continental countries, scutching is almost invariably performed by hand, the flax being held in a groove made in an upright stand, and struck by a flat blade. Machine-scutching is much more certain and expeditious than hand-scutching, and is, in consequence, fast superseding it in this country. After passing through the breaking-machine, the flax is subjected to the action of a series of knives, *b*, *b*, attached to the arms of a vertical wheel, *a*, fig. 2; these knives strike the flax in the direction of its length. A side view of the arms and knives is shewn at *c*, *c*, fig. 2. The process is

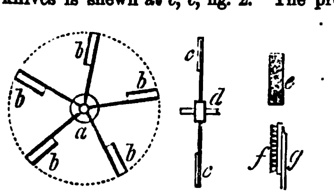

Fig. 2.

gone through three times before the flax is ready for the market. Although machine-scutching is expeditious, it is not capable of that pliant adaptation to the varying nature of the flax to be operated upon, which is obtained in hand-scutching. The effect of machine-scutching is to produce fineness by reducing and impairing, rather than sustaining, the character of the fibre—namely, the length and fineness of its 'staple' or fibre. To remedy these defects, Mr Plummer introduced scutching by means of revolving brushes, rather than by the hard unyielding blades or knives of the ordinary machine. In one form of machine on this principle, a series of flat brushes are arranged on the two faces of a disk, which revolves in a case. The flax to be operated upon is held in what is termed a *holder*, and receives from the brushes a succession of mild and penetrating strokes, which divide the fibre without tearing it. Mr Plummer has applied the principle to hackling machines with considerable success.

The diagram to the right of fig. 2 shews part of the disk, *g*, to one side of which brushes (of which one is seen at *f*) are attached: *e* is a front view of the brush *f*.

After being scutched, the flax is made up into *stricks*, or bundles, and taken to the next process, which is the first of what are strictly called the 'manufacturing operations.' The bundles are usually composed of fibres some twenty-six to thirty-six inches long; the part nearest the ends is of least, that nearest the centre of the fibre of the highest, value. To obtain the most valuable portion of each strick, it is separated into three, sometimes four parts, by means of a machine, of which fig. 3 is an illustrative diagram. In the centre of the framing, a wheel, *aa*, is supported on a shaft or axis; the periphery of this is furnished with a series of projecting or cutting edges of an elliptical form.

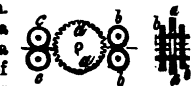

Fig. 3.

On each side of this cutting wheel, two pair of grooved rollers, *bb*, *cc*, revolve. An end view is given to the right of the cut, in which only the set of rollers at one side, *b*, *b*, are visible. The stricks are held stretched between the adjacent pairs of rollers, *b*, *b*; and the revolution of the rollers advances the flax sidewise against the cutting edges of the wheel, so that it is divided into two lengths, the one, however, being shorter than the other. The longer of the two parts is passed through the machine a second time, and thus each strick is divided into three lengths, of which the middle portion is more valuable than the two end portions. The three lengths thus obtained are laid on separate heaps, to be ready for the succeeding process of *hackling*.

The object of this is thoroughly to clean the fibres of all dirt, and to parallelise them, the cleaned portion being termed *line*, the refuse *tow*, which last is used for coarse sacking, &c. Hackling, as performed by hand, is as follows:—The hackle is a strong comb, composed of several rows of steel teeth, four or five inches in length, fixed upright in a block of wood as a base, and made fast to a bench, fig. 4. The workman taking a handful of scutched flax, strikes it against the pointed summits of the teeth, and draws it through—repeating the process till the requisite fineness is obtained.

Fig. 4.

Coarser and wider-toothed hackles are first used, and then others progressively closer as the fibres become finer by separation.

The process, however, is now almost universally effected by machinery, the nature and operation of which may be briefly described. The hackling-points are arranged in bands, or alternate rows, *a*, *a*, fig. 5, round the circumference of a cylinder, *bb*; the rows of points are of different finenesses—the row at one end being coarsest, the next finer, and so on. The flax to be operated upon is suspended above the cylinder by means of a holder, *c*.

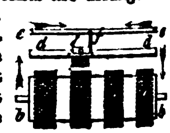

Fig. 5.

The process is threefold—first, as the end of the strick of flax depending from the holder is required to be hackled less than the middle portion, the strick is made to rise from, and approach to, the hackling-points; as the strick falls, the hackling-points pass through the ends, obtaining a deeper hold the lower the strick descends, and the thicker portion comes in contact with the teeth; and *vice versâ*. The strick is made to rise and fall as thus described, by placing the holder which carries it upon a *table*, *dd*, which, by means of a cam-movement, is made to rise and fall as desired. The second movement desiderated, is the pushing of the holders with their stricks along the table, to put the flax successively in contact with the rows of hackle-teeth of different gradations of fineness. This is effected in a variety of ways by ingenious machinery, for a notice of which we refer the reader to the *Artisan* for 1851, in the October and following numbers. One method adopted is illustrated in fig. 5. The rod *ee* has an alternate lateral movement, as shewn by the arrows; fingers, one of which is shewn at *f*, are jointed to the under side of this, and hang downwards. They are prevented from

moving in one direction by means of a snug or projecting part attached to *ee*. As the rod *ee* moves in one direction, the fingers give way, and slide over the top surface of the holders; but on its moving in the other direction, the fingers come in contact with the ends of the holder, and being prevented from moving by the snug above mentioned, they press against the holders, and move them along the table *dd*. The third movement required is to place the flax so that both sides of the strick shall be subjected to the hackles. As the hackles revolve always in one direction, it is necessary to turn the stricks after passing through the machine, before sending them a second time through. This, in many machines, is effected by hand; but in Carmichael's, the strick is made to give a semi-revolution by ingenious mechanism; while in Plummer's patent machine, both sides of the strick are hackled at once, by allowing the strick to be suspended from the holder, *c*, between two revolving cylinders, *a*, *b*, fig. 6, in the peripheries of which are fixed a series of brushes.

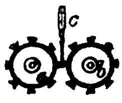

Fig. 6.

The flax is next passed through the 'spreading-machine'—the object of which is to bring the fibres into the condition of a long, narrow band, of uniform thickness. As the stricks from the hackling-machine are of different thickness, they are spread upon a table, *c*, fig. 7, the thin part of one being placed against the thick part of another. The sheet of flax thus prepared is passed between a pair of rollers, *a*, *b*, on to a series of upright hackle-teeth, represented by the line *h*, which have a progressive movement from the front to the back of the machine; these teeth still further comb and parallelise the fibres as they are moved onwards to a second pair of rollers, *d*, *e*, which, revolving faster than the first, *draw* out or lengthen them. The thin sheets of flax from the different rollers are passed in fours through slits made in the back plate of the machine, and being united into one, are finally passed between a pair of rollers, *f*, *g*, and delivered to a tin can. The progressive movement of the hackle-teeth, represented by the line *h*, in fig. 7, is effected by two methods, one of which is known as the 'sheet,' and the other the 'screw' 'gill.' The operation of the latter, which is considered the most effective, is illustrated by the diagram in fig. 8. On each side of the spreading-machine, fig. 7, two endless screws revolve in bearings one above the other, as 1, 1, 2, 2. There are thus two pairs, one on each side. The upper and under screws are placed parallel to one another, as *aa*, *bb*, fig. 8. Bars, as *c*, *d*, are so made as to pass at their extremities between the threads of the screw, and are thus made to progress in the direction of the length of the screws, as at *f*. The upper surfaces of the bars are provided with hackle-teeth. As each bar arrives at the end of the screw, it drops down to the position of 2, 2, fig. 7; the lower pair of screws revolving in the opposite direction, take the bars in the direction of the arrow *g*, fig. 8; on reaching the end, they are lifted up to the upper pair of screws—as 1, 1, in fig. 7. By this means, a continuous array of hackle-teeth is made to pass along between the rollers *ab*, *de*, fig. 7. The subsequent processes of *doubling*, *drawing*, and *spinning* are all nearly the same as in the cotton manufacture, afterwards described in this paper. The only difference is, that in spinning flax the slivers are previously passed through hot water of 120°; this is necessary, as they have not the same tendency to combine as the fibres of cotton. Weaving being a process common to all the textile fabrics, of the nature of cloth, will be described when speaking of the woollen manufacture.

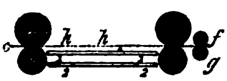

Fig. 7.

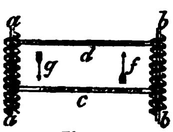

Fig. 8.

The *tow*, which may be termed the refuse of the manufacturer, being somewhat analogous in nature to *cotton*, is prepared by machines resembling those used for this material.

In the majority of flax-mills, the operations cease with the spinning of the fibres into the yarn, and the weaving is effected elsewhere, chiefly by hand-looms; although there are many factories in which linen-cloth is manufactured by the aid of the power-loom.

The chief seats of the linen-cloth manufacture are, Belfast in Ireland, Barnsley in Yorkshire, and Dundee and Dunfermline in Scotland. In Barnsley, the fabrics manufactured consist of linen, huckaback, diaper, duck, check, drabbet, tick, towelling, and union, a mixture of the staple with cotton. The fabrics made in Ireland are coarse and fine linens, canvas, sacking, and damask. The manufactures at Dundee are mostly confined to coarse linens, sailcloth; while at Dunfermline, fine shirtings, damasks, and table-cloths, &c., are the principal fabrics made.

Bleaching and *calendering* are the processes which follow the weaving, and in both there are now great improvements. The principles of bleaching have been already explained under APPLIED CHEMISTRY—whether by the old process of sun-bleaching on the grass, or by the application of chemical detergents. The following is a brief description of the process as followed by the Irish manufacturers. Taken from the 'pieces' which come from the manufacturer, and loosely knotted, the cloth is passed into a boiler or vat, along with a weak solution of potash. Boiled for several hours, it is transferred to a wash-mill, and subjected to the action of a stream of water, constantly passing through. The cloth is worked up and down in the mill by heavy wooden stampers, having an alternate motion given to them by means of a revolving cylinder furnished with projecting pegs, which lift the stampers up at intervals. From the mills, the cloth is removed to the green, and spread out, the lengths being roughly stitched together. They are retained in their place on the ground by means of pins. Allowed to lie here for two or three days, the cloth is again subjected to a series of boilings and washings. It is then passed through the 'rub-boards,' the surfaces of which are provided with hard wood cut into parallel grooves. The boards are moved backwards and forwards by simple mechanism, with the linen between them, plentifully soaped. The entire web is thus submitted to friction. The cloth is next steeped in vats, in a solution of weak sulphuric acid. The finishing processes then commence, which vary according to the fancy of the manufacturer—some smoothing by heated cylinders, others using starch and similar ingredients to stiffen the fabric, and not a few employing more objectionable methods of stretching, smoothing, and producing an artificial gloss, with a view to make an inferior fabric assume the appearance of one of superior quality.

Before concluding this part of the subject, we think it right to notice the important innovation in flax manufacturing introduced by Chevalier Claussen, well known as flax-cottonising, and which, although it has not yet been very successfully carried out, bids fair, in the opinion of competent judges, to form an important feature in our manufactures, when once experience has dictated improvements in the process, and the commercial and other difficulties always attendant upon the introduction of any innovation been fairly overcome.

The flax is in the first instance passed through a machine, which separates the woody core, leaving the fibres still held together by the gummy resin; from which they are next freed by being boiled in a weak solution of caustic soda. Where the fibres are required to be long, for manufacturing by ordinary flax-machinery, the flax is subjected to the action of a bath of weak sulphuric acid, which removes the alkali of the previous operation. It is then bleached. If it is desired to be adapted for spinning by cotton-machinery, so as to be

mixed with cotton, wool, or other fibre, the following processes are gone through:—The long flax fibres are cut into short lengths by a machine similar to a chaff-cutter. Taken out of the soda-vat already mentioned, the short lengths are next placed in another, containing a solution of bicarbonate of soda; remaining in this till fully saturated, the flax is taken out and subjected to the action of weak sulphuric acid. The result which ensues is singular. The hollow fibres saturated with the salt are brought in contact with the sulphuric acid; carbonic acid gas is immediately formed, and a series of explosions, as it were, take place, which split or blow up the fibres into beautiful filaments, closely resembling raw cotton. The material thus obtained is well adapted to be worked up by cotton machinery; and mixes well with cotton, wool, and silk, and takes, in addition, dye with considerable facility. A variety of useful mixed fabrics can thus be made. If the results held out by the advocates of this process can be realised, it will have an important influence on the cultivation of flax in Great Britain.

Prior to the introduction of machinery, the linen trade was very limited in extent. On the introduction, however, of improved mechanism, it increased rapidly. Mr Marshall stated that the trade had doubled in England, and trebled in Scotland, in the course of half a century. In 1850, the exports of linen-yarn amounted to £887,295. The importation into this country of flax and tow, in 1850, amounted to 1,821,578 hundredweights. In 1852, the consumption of flax fibres was about 150,000 tons, of which it was calculated that not more than a fourth was grown at home.

According to the Return of the Board of Trade, the declared value of the exports of the linen manufacture in 1852 was £4,231,786, and in 1853, £4,761,252. Linen-yarn was exported in 1852 to the extent of 23,928,592 pounds, value £1,140,565; in 1853, the number of pounds was 22,782,661, the value, £1,149,103.

The most recent Factory Return, of date 15th August 1850, presented to parliament, states the number of flax factories in the United Kingdom at 393—of which England and Wales possessed 135, Scotland 189, and Ireland 69. The number of spindles in the 393 factories amounted to 965,031, and the power-looms to 3660, absorbing a power of 10,905 horses in steam and 3387 in water power. The total number of hands employed was 68,434; of which 47,617 were females, and 20,817 males.

Hemp and other Ligneous Fibre.

Hemp is the fibrous bark of the *Cannabis sativa*—a plant supposed to be a native of Persia or India, but which has long been naturalised and extensively cultivated in Europe, particularly in Italy, Russia, and Poland, where it forms an article of primary commercial importance. It is also cultivated to a considerable extent in many parts of America; but in Britain it is but little grown, except in a few districts of Suffolk and Lancashire. Its fibres are prepared for spinning in the same way as flax, and are made into yarn for the fabrication of canvas-bagging, sailcloth, ropes, and cordage. The common cultivated *hop*, some species of *nettle*, and other plants belonging to the same natural order (*Urticaceæ*) as the hemp, yield also a tough elastic fibre, from which coarse fabrics are occasionally woven. Indeed, the elaboration of a tough elastic product seems to be characteristic of the whole order—making its appearance in the stem of the hemp, in the inspissated sap of the India-rubber tree, and in silk, the best of which is derived from silk-worms that feed on the leaves of the mulberry. Several of the members of another natural order (*Liliaceæ*) yield fibre strong enough to be worked into cloth and cordage; but in these the fibre resides in the leaf, and not in the bark of the stem. Of these may be mentioned the *New Zealand Flax* (*Phormium tenax*), whose toughness rivals that of hemp, and the *Sansevieras*, from which is obtained the still stronger substance called *African* or *bowstring hemp*. *Coir*, which is extensively worked into mats and cordage, is the dry fibrous pericarp of the cocoa-nut. The inner bark of various trees is sufficiently tough in fibre to form material for fishing-lines, nets, rice-bags, a coarse kind of linen, and the well-known matting called *bast*. The linden-tree may serve as an example, its inner bark furnishing the Russian or bast mats so largely employed for commercial purposes. The most of the coarse fabrics so composed are either woven or plaited; ropes and cordage are twisted on the same principle as common thread, either by hand-labour, or perhaps now more generally by machinery.

COTTON.

The cotton-plant is of the order *Malvaceæ*, its type being the common mallow. The genus *Gossypium* is that which produces cotton, comprising, according to various authorities, from five to ten species, all natives of intertropical climates, and indigenous to India and America. The numerous varieties of these species have their origin in peculiarities of soil, climate, or locality. The most useful species, and the one generally cultivated, is the *Gossypium herbaceum*, or herbaceous cotton-plant. It is an annual, the average height being twenty inches. Each leaf is divided into five lobes, the colour darkish green, streaked with brown veins. The flower is of a palish yellow, like the mallow; the petals are five in number, each having a purple spot at the base. On the flower falling off, a capsular pod is seen supported by three triangular leaves, having deeply indented edges; the pod is triangular in shape, of the size of a walnut, and is divided into three cells. As the pod ripens, the expanding wool bursts it, and exposed to view appears a ball of yellowish or snow-white down, which is divided into three parts, a part belonging to each cell. When thoroughly ripe, the operation of gathering is carefully gone through. As the plants do not ripen uniformly, the operation of picking has to be repeatedly gone through, warm fine weather being always chosen, never wet or damp. After being picked, the cotton or wool, as it is called, is laid to dry in the sun.

The qualities of cotton used for manufacturing purposes are various; the most valuable is that known as 'Sea Island,' which is cultivated on the low marshy islands and plains on the coast of Georgia and South Carolina, in the United States of America. The staple of this quality is long and silky. The short-stapled quality, known as Bowed or Upland Georgia, is produced in immense quantities in America. Cotton of good quality is imported from Egypt, where its cultivation was begun by Mehemet Ali in 1823. The supply obtainable from the East Indies is fast increasing in amount: when railways and canals open up the interior of our possessions there, and when as much care is taken in its cultivation and cleaning as is done in America, we may reasonably expect that our manufactories will be supplied to a large extent, if not exclusively, from these our own possessions. The West Indies also supply us with cotton. Brazilian cotton was first imported in 1781. Pernambuco cotton is very valuable, generally fetching a price next to that of Sea Island.

The value of cotton for manufacturing purposes is reckoned by the length, strength, and fineness of the staple, or fibres. The 'long-stapled,' or valuable cottons, are Sea Island, Brazilian, West Indian, Egyptian; the 'short-stapled,' or inferior qualities, are the Upland cotton of America, the Orleans, Mobile, and Surat.

Within the limits of our paper, it is impossible to trace the early history of the manufacture in the land of its birth in India, its extension to Arabia, to Spain, and ultimately to England. It is to a brief notice of its progress in this our own country that we will devote the short space at our command.

Some statements occurring in our early chronicles, would make it appear that an antiquity of 300 years

could be claimed for our English cotton trade. In Leland's *Itinerary* (1538), mention is made of the *cotton* trade of Bolton; and in a statute of Henry VIII., of that of Manchester. It appears, however, that these allusions had reference to woollen manufactures; as in sundry documents mention is made of processes in reference to *cottons* which are applicable only to woollen. Authorities conceive that the reason why *woollen* goods were termed '*cottons*,' was in consequence of the fabrics which they imitated being of foreign manufacture and made of cotton.

The first authentic proof we have of the existence of the cotton manufacture in England, is a notice in a work published in 1641, in which the existence and importance of the trade, as carried on at Manchester at that period, is specifically mentioned. The progress of the trade was remarkably quick; in 1727, the population of Manchester, then, as now, the seat of the manufacture, had doubled.

In 1697, the quantity of cotton imported was about 2,000,000 of pounds; it took fifty years to increase this to 3,000,000; the next fifty years shewed a more satisfactory rate of progress, the importation at the end of that period amounting to 56,000,000. In 1850, the quantity imported amounted to nearly 525,000,000. In 1785, the first bag was brought from America. The quantity obtained from that country in 1850 was nearly 2,000,000 bales. A bale weighs, on an average, 300 pounds, the price per pound varying from 7¼d. to 5½d. The average weekly consumption of the whole kingdom may be set down at 30,000 bales. In 1679, the total value of cotton goods exported was nearly £6000; in 1850, it reached a grand total of upwards of £28,000,000; and for the *seven months* ending August 1854, the declared value of cotton goods of all kinds exported was no less a sum than £18,601,374, or at the rate of £36,000,000 a year.

The introduction by Arkwright of the method of spinning by rollers was the turning-point in the history of the trade. Previous to this, the demand for yarn for weaving was always greater than the supply. But with the unlimited supply of the new process came also the increase of weaving. In 1850, the number of spindles at work throughout the kingdom was 21,000,000. In 1803, the first practical power-loom was introduced by William Horrocks of Stockport. In 1817, about 2500 only were in use; in 1835, this had increased to 116,801; and in 1850, to 225,000. In 1760, the manufacturing population was estimated at 40,000; in 1835, it had increased to 260,198; and in 1850, reached 332,124. In 1833, the number of mills in the kingdom was 1154, taking up a power of 41,000 horses in steam-engines and water-wheels. In 1839, the number of mills had increased to 2019; the horse-power to 59,856.

According to the Factory Return already quoted in the section on flax, the number of cotton-factories in the United Kingdom was 1932—of which England possessed 1753, Ireland 11, and Scotland 168. The amount of horse-power in steam employed in the 1932 factories was 71,005, and in water 11,550, giving motion, amongst other machinery, to 20,977,017 spindles, and 249,627 power-looms. The number of males employed was 141,491, and females 189,423.

We now proceed to detail the practical processes of the manufacture. The first of these we notice is that of separating the seed from the cotton, which is always done in the country in which it is raised. In America, the cleaning is effected by the roller-gin and the saw-gin. The first is a simple arrangement of two rollers having fluted peripheries, revolving nearly in contact. The cotton is passed between these, and the seeds, separated, fall down. Fifty pounds per day is the maximum amount of work of which this machine is capable. The saw-gin is the most efficient mechanism; and, from the immense amount of work it is capable of doing, it has had the same influence in extending the cultivation of cotton in America as the spinning-rollers had in extending the cotton manufacture in this country. The cotton to be cleaned is put into a hopper, *a*, fig. 9, the bottom of which is sloping, and is composed of bars of iron, *bb*, an eighth of an inch apart. Between these a series of circular saws, *c*, fitted on a roller, revolve; the teeth projecting a little above the bars, catch the cotton, and tear it open, the seeds sliding down the grating. The wool is stripped from off the saws by a brush, *d*, revolving rapidly against the teeth, and in the opposite direction to that of the saw. The cotton thus cleaned, is pressed into compact bales by the hydraulic or a screw press, and thus shipped.

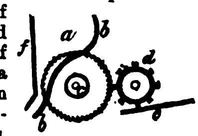

Fig. 9.

Arriving in England in a state far from clean, being mixed with a variety of extraneous matters, and the fibres much matted together, the cotton has to be further subjected to a cleaning process. This is effected by the *willow*. A large conical drum rotates rapidly on a horizontal shaft, and is provided with a number of projecting spikes; the drum is covered with a case, in the inside of which are a number of spikes, so arranged as to pass between those in the drum as it revolves. The cotton is fed by an endless *apron*, at the smaller end of the cone, and is dragged between the spikes up to the larger end, where it passes into a case, from whence it is withdrawn by hand. The rapid rotation of the cone creates a sufficient draught to carry off the dust through a pipe. A machine called Hardacre's cotton-opener is becoming much used instead of the willow. Two vertical shafts, *aa*, *bb*, fig. 10, rotate rapidly within a case, the sides of which have openings, leading the dust, &c., to a series of cells. The vertical shafts are provided with horizontal arms, which rapidly strike and open up the cotton, which is fed from the top, at *d*.

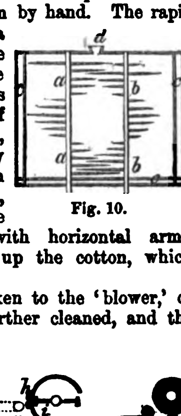

Fig. 10.

The cleaned cotton is now taken to the 'blower,' or 'scutcher,' fig. 11, where it is further cleaned, and the fibres separated one from another. The cotton being fed by the apron, *a*—made of a series of thin narrow wooden bars, fixed at their ends to two strips of leather revolving round rollers at each end—it passes between two pair of feed-rollers, *b*, revolving nearly in contact. On issuing from between the last of these, it is struck violently by the arms of a rapidly revolving beater, *c*, making some 1800 or 2000 revolutions per minute. The impurities pass from the cotton, and fall upon an inclined grating, *ee*, the cotton being wafted along to a second apron, *gg*, with a second set of feed-rollers, *h*, and again struck by revolving beaters, *i*, and finally passed to the floor. It is next taken to a second blower, similar in all respects to the former, excepting that instead of being delivered to the floor, it is passed through feed-rollers, *k*, and finally wound upon large rollers in the form of a continuous lap, *l*; hence the name of the machine, the lap-machine. In many cases, however, the blower and lap-machines are combined in one. The grating already mentioned is composed of thin bars of iron, set angularly, so as to present a series of edges to the cotton as it is whirled about by the beaters, thus further opening it. Between the first and second

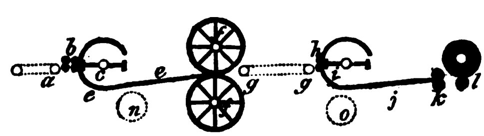

Fig. 11.

beaters, *c*, *l*, are two revolving hollow cages, *f*, *f*, with perforated periphery; the cotton is wrapped round this before being delivered to the second feed-rollers. A strong draught is created in the machine by fans, *n*, *o*, which aid in carrying off all the dust, &c., to the external atmosphere.

The action of all machines noticed has been to open the fibres of the cotton, and clear them of adhering matter. This, however, has brought about a condition of matters not desiderated in the after processes—namely, a complete confusion of the fibres, causing them to lie in all directions one to another. It is the duty of the following machines to bring all the fibres parallel to one another. The more complete the parallelisation, the higher the quality of the yarn obtained.

If the reader will take a quantity of loose fibres of cotton, confused and twisted together, and place them between two brushes, and move the brushes parallel to one another, but in opposite directions, repeating the process several times, he will find the fibres lie parallel to one another. This is exactly the carding process. The teeth of the brushes or cards are, however, fixed upon revolving surfaces, and are not straight, but bent, as *a*, fig. 12. The revolving teeth act against the teeth of other cards fixed on a curved surface, and the inclination of which is in an opposite direction. There are two arrangements of carding-engines in use. In the first, a large cylinder, *bb*, fig. 12, rotates rapidly, provided on its surface with a series of strips of leather, in which the wire card-teeth are fixed. These rotate in close contact with a series of cards called flats, *c*, *c*, fixed in the inner side of the outer casing, which is of the same curve as the large cylinder. In the second arrangement, the large cylinder is retained; but it works in contact with a series of small cylinders, provided with card-teeth, which rotate less rapidly than the large cylinder: these are termed squirrels or urchins, or strippers and clearers. The flat and urchin systems are sometimes combined in one. The operation of the carding-machine on the combined system is as follows:—

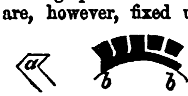

Fig. 12.

The lap-roller, *b*, fig. 13, with its length of cotton-lap wound round it, is placed at the end of the machine, in bearings—the lap is withdrawn from this by two feed-rollers, *c*; it is then taken up by a small cylinder, *d*, furnished with card-teeth, and called the 'licker-in;' from this it is taken up by the large carding-cylinder, *a*, and delivered to the small strippers, *f*, *f*, which, rotating with less speed, hold the fibres to allow the large cards to act upon them; the flats, as *c*, *c*, fig. 12, also take the fibres up, the process being a continual delivering and redelivering from the large cylinder to the small ones and the flats. The cotton is ultimately taken from the large cylinder by another, termed the doffing-cylinder, *g*, on which the cards are fixed in spiral lines. To take the cotton from this is the work of the doffing-knife, which is a long flat blade, with one edge serrated, fixed at the ends to two connecting-rods, *h*, which have a quick up-and-down motion given to them by cranks at their lower extremities. The action of the knife is to strip off the cotton from the doffing-cylinder, in a sheet of extreme lightness. This is gathered up, passed through a trumpet-mouth, *o*, and finally between revolving rollers, *m*, so as to form the cotton into a long, flat, and narrow ribbon, which, by means of ingenious mechanism, is coiled into long narrow cans, in such a way as to occupy the least possible space. Two kinds of carding-engines are used in the manufacture—the breaker and the finisher. In the former, the cotton, after being carded, is delivered to rollers, and finally wound in a continuous sheet on a lap-roller. This 'lap' is carried to the 'finisher' carding-engine, through which it is passed, and finally coiled in the can, as above described.

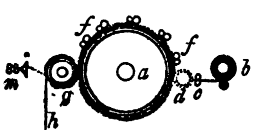

Fig. 13.

The next process is that of 'drawing,' the object of which is still further to parallelise the fibres. Let a tuft of cotton fibres be taken, and separated by means of the fingers; by repeating this process for some time, it will be found that the confused fibres will lie parallel to one another. Suppose three pair of rollers to revolve near one another, and a thin ribbon to be passed between them—if they all revolve at the same speed, the ribbon will go through unaltered; should, however, the last or third pair revolve faster than the first and middle pair, the ribbon will be pulled out or elongated somewhere between the first and third. This is the arrangement of the drawing-frame. In practice, the rollers revolve all at different speeds—the third faster than the second. This is the arrangement of the rollers in the finisher carding-engine. The drawing-frame, in which the process is more specially carried out, consists of a series of rollers, *aa*, *bb*, *cc*, fig. 14, the upper of which are covered with leather, and the lower fluted. A flat board, *d*, faced with flannel, presses on the upper rollers, by which they are cleared of all loose fibres. A number of slivers from cans, generally eight, are united into one, and passing over a grooved brass plate, are taken up by the rollers, and finally delivered to a can from between the rollers, *e*. The process not only parallelises the fibres, but tends to equalise the quality of the cotton, making the slivers of uniform strength and texture, by combining many slivers into one. This, which is called 'doubling,' is repeated until all defects are got rid of, and a uniform sliver obtained. Thus, in the first instance, eight slivers are passed through one set of rollers, increasing the chance of uniformity eight times—if four of these are again made into one, the chances are increased thirty-two times, and so on, till the last sliver may contain parts of 300 slivers. The process, however, for fine spinning is carried to a much higher rate of multiplication than this, sometimes exceeding 60,000 times. The distance between the rollers is regulated by the length of the staple. As all the cans sent from the drawing-frame must have the same length of sliver in each, should any of the slivers break, it is of importance that the machine should be stopped at once. This is effected by the machine itself, by the 'patent-stop motion.' The sliver passes to the rollers over a nicely balanced lever, which is kept in position by the friction of the passing sliver; when it breaks, the lever falls out of position, releases a lever which acts upon another lever, and passes the driving-belt from the fast to the loose pulley, and stops the machine. The drawing-frame is of considerable length, containing several sets of drawing-rollers.

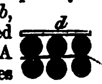

Fig. 14.

The machine next used is called the roving, or slubbing, or bobbin and fly frame; the duty of which is to give the loose, porous, thick cord from the drawing-frame a certain amount of twist, to enable it to be wound upon large bobbins. A series of spindles, *b*, *b*, fig. 15, are made to rotate with great rapidity vertically; these pass through a board, *d*, upon which rest a series of bobbins, *a*, up the central tube of which the spindles pass. The bobbins are made to rotate independently of the spindles, and at a different speed. To the top of the spindle, a fork is attached, the ends of which are bent downwards, so as to be on each side of the spindle like the letter

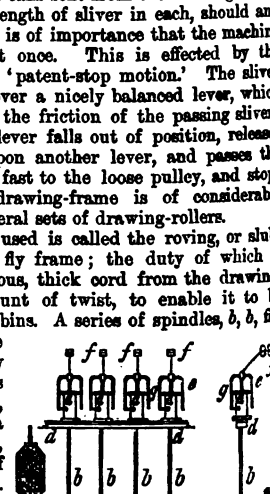

Fig. 15.

U reversed, as *eg*. One arm, *g*, of this fork is hollow, and has at its lower extremity a delivering or spring finger. The sliver is passed from the drawing-rollers, *f*, attached to the frame down the hollow tube, *g*, of the fork, *eg*, and passed round the bobbin, *a*; the machine is now ready for operation, which may be described as follows:—The degree of twist and winding in is entirely due to the difference of speed between the spindle and its attached fork, and the bobbin rotating on the spindle. The revolutions of the fork give the twist, the difference of speed between the bobbin, and the spindle gives the quantity wound on the former. If the finger always remained at the same height, the cotton would be wound up at one place of the bobbin only; to distribute it equally over its surface, the frame on which the bobbins rest moves up and down. As the diameter of the bobbin increases, it is necessary, in order to lay the roving equally on, to decrease the speed—the decrease of speed being proportioned to the increase of diameter. This is effected by having a conical drum, the belt of which works the drum giving motion to the bobbins; as the belt passes from the small end of the conical drum to the large, its velocity decreases. The speed of the spindle and of the delivering-rollers being always equal, the quantity of roving delivered to the bobbins is always uniform; hence, as the bobbin surface increases in diameter, its velocity must be decreased, to enable the same quantity as before to be laid on during the same time. In place of winding the yarn round bobbins, as at *a*, *a*, it is sometimes wound round cylindrical spindles without ends, and made to assume the form shewn at A, fig. 15.

The bobbins, when full of roving laid uniformly on, are taken off the spindles by removing the fork, and put into skips, made of buffalo-hide, wicker-work, or gutta-percha, and conveyed to the next process.

The rovings thus produced are spun into hard, well-twisted yarn by two machines, the throstle and the mule; the former generally spins the harder kinds for the warp, and the latter the softer for the weft of woven goods. In the throstle, the arrangements are very similar to the roving-frame, with this exception, that the bobbins have no independent motion given to them by special means, the difference between the speed of the bobbins and the flyers or forks being caused by the friction of the bottom of the bobbins revolving in contact with a board faced with flannel; this board is called the copping-rail, and moves up and down, to distribute the yarn equally over the surface of the bobbins. The yarn drags the bobbin after it, but the weight of this and its friction on the rail keep it back, thus giving the twist by the difference of the speed.

In the mule, the yarn is not wound upon bobbins, but round steel spindles, and is built in such a way as to be thickest near the middle, gradually decreasing in diameter towards top and bottom; the bottom part, however, being much shorter than the upper, as shewn at *klm*, fig. 16. The mule consists of two essential

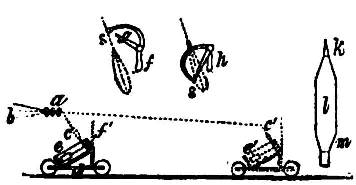

Fig. 16.

parts, one of which is fixed, and contains a row of bobbins from the fly-frame, ranged on a series of spindles, allowing them to rotate as the yarn is drawn from them. On the fixed head, the sets of drawing-rollers, *a*, are fixed. The other part of the mule is the carriage, *d*, which moves to and from the fixed head on parallel rails. The carriage carries a range of spindles, *c*, sometimes 1000 to 1200 in number. On these the yarn is laid to form cops, as they are termed. The spindles are made to revolve rapidly by bands passing from drums, *e*, round pulleys, or 'wharves,' fixed at the lower extremities of the spindles.

To the carriage standards are fixed, carrying a horizontal shaft parallel to the line of the spindles. This shaft is provided at intervals with curved arms, *g*, *h*, fig. 16; these supporting a slender wire, as *s*, *s*. The shaft to which the arms are attached is movable, so that the arms can be brought from the position at *g* into that shewn at *h*. The operation of the machine is as follows:—The carriage is brought up to the 'head;' the drawing-rollers, *a*, give out the yarn, which is wound round the points of the spindles, *c*, the faller-wire, *gs*, being in the position shewn at *sgf*; the carriage then moves outwards at a rate quicker than the yarn is delivered by the rollers, so as to stretch and equalise it; the drawing-rollers, when the carriage has gone out to some fifty or sixty inches, or a 'stretch,' as it is termed, cease revolving, so as to hold the yarn firmly. The motion of the carriage is greatly reduced in speed, while that of the spindles is accelerated; by this means the required twist is given to the yarn. On the carriage leaving the head, any yarns which may have broken are pieced or mended by little children, called piecers. The carriage is now disengaged from the mechanism which moved it on the rails, and the spinner begins his work. This consists of three operations, all of which must be done simultaneously, and with great nicety, to proportion all the movements to one another, on which the fineness and value of the yarn depend. These operations are—the pushing in of the carriage with his knee towards the head stock, or roller beam; placing the faller-wire in the position shewn at *hsf*, fig. 16, so as to bring all the threads to the level of the bottom of the cop; and, lastly, to turn a wheel, by which motion is given to the spindles, at a speed proportionate to the movement of the carriage. Previous to performing these operations, he causes the spindles to revolve in the wrong direction, so as to throw the yarn off the points of the spindles, which was delivered to them during the stretch last completed. On approaching the head, the attendant brings the faller-wire gradually up to the position shewn at *gsf*, fig. 16, thus preparing for another stretch. The carriage mechanism is then put in gear with the main driving-shaft, and the operations above described are again gone through. Thus, by a succession of operations, the yarn is finally built up into cops, which, when finished, are stripped from the spindles, and put into baskets. In the self-acting mule, all the operations are done by machinery, and the only attendance required is that of piecers and menders, the latter being adults. The following illustration shews a range of mules at work.

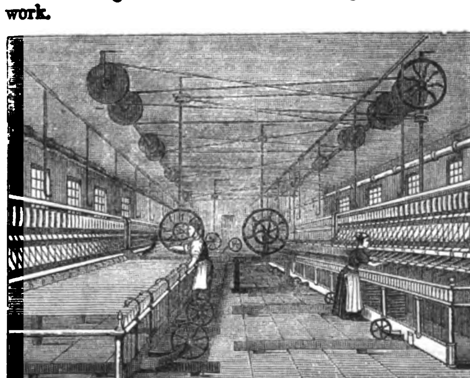

Fig. 17.

To be ready for weaving purposes, the yarn from the

bobbins or the cops is placed upon larger bobbins by the winding-machine, in which the small bobbins from the throstle, or cops from the mule, are placed either vertically or horizontally. The threads from these pass through glass 'eyes' or hooks, fixed to a guide-bar, which has a lateral to and fro movement given to it; and are thus evenly wound upon the surface of the large bobbins. These are taken and placed horizontally on axes placed in the frame, *d*, of the warping-mill, fig. 18. The threads or yarn from a number of these are passed through glass eyes, in a heck-box, *e*; which is suspended by a cord passing over a pulley, the termination of which is wound round the main axis of the upright skeleton framework, *aa*. As the latter revolves, the cord is wound round the axis, and gradually raises the heck-box upwards. On the framework revolving in the contrary direction, the cord is unwound, and the heck-box descends. By this arrangement the yarns are wound spirally round the frame, the circumference of which is so designed that it serves as a measure of the quantity wound upon it. Motion is given to *aa*, by the crank *c*, and pulley *b*. The heck divides the yarn into two sets, one for each heald of the loom.

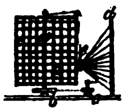

Fig. 18.

The sets, or the 'lease,' of yarn are taken off the frame and wound up in a ball, and taken to the beaming process. The yarn in this is laid on cylinders or beams, and each thread distributed equally, by passing through between shreds of cane fixed in frames. The warp thus formed, is next dressed in the dressing-machine, by which each thread or yarn has a portion of flour-size well rubbed in by brushes and rollers into its fibres. When dried, the warp is stiff, and easily drawn through the healds of the loom, for which it is now prepared. The supply of yarn in the shuttle is always derived from a cop, so that yarn for a weft is never made in the throstle, but always in the mule. We shall, under the head of Wool, describe the movements of the ordinary loom, so that it is unnecessary here to advert to the movements of the *power-loom*, which are exactly similar, but produced by steam-power instead of manual labour. In the annexed engraving is presented a view of the interior of a power-loom apartment. All the looms are of iron, and moved by belts from shafts, the shafts being turned by steam or water power.

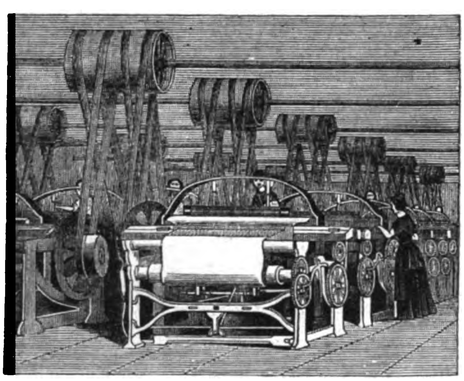

Fig. 19.

SILK.

This beautiful and unrivalled material is the produce of a plain-looking, greedy, leaf-devouring larva—the caterpillar of the silk-moth, or *Bombyx mori*. It is thus directly of animal, though indirectly of vegetable origin; the glutinous caoutchouc principle of the leaves furnishing the worm with the basis of its silken fabric. The silk-worm is supposed to have been indigenous to China; at least the discovery was there first made that the product of this little creature's operations could be elaborated into articles of human attire, richer and more beautiful than any to be derived from other sources. At an early period, a considerable commerce was established in silk between Eastern and Western Asia, from which latter quarter it was conveyed to Europe; but not until the sixth century of the Christian era was it distinctly known by Europeans that the splendid tissues which they had worn for more than a thousand years, and which they had even partially manufactured from the raw transported material, were the product originally of a caterpillar. The first silk-worms seen in Europe were brought from China in the year 552, by two Persian monks, who had gone thither as Christian missionaries, and who contrived to secrete a number of the eggs in a cane, and to escape with them to Constantinople. From these few eggs have sprung all the successive generations of the insect which have supplied silk to Europe from that period to the present time.

As our paper is confined to notices of the *manufacture* of the various materials, not of the processes by which they are cultivated, as in the case of cotton or flax, or produced, as in silk and wool, we pass over the points connected with the rearing, feeding, and treatment of the worm, prefacing our more practical remarks by a notice only of those a knowledge of which is necessary to the due understanding of the processes of manufacture.

The silk, which is the produce of the silk-worm, is passed through two small holes in its head; the two filaments thus passed out, by a combined movement of the mouth and front legs of the animal, are combined into one, being bound closely together by a gummy liquid. This long filament, extending sometimes to a mile, is spun into the shape of an egg-shaped ball, in the interior of which the worm is enclosed. When its labours cease, we have what is called a silk cocoon, from an inch to an inch and a half in length, and of a pale-yellow or orange colour. The cocoons are next subjected to heat, which kills the worms imprisoned within.

The exterior of the cocoon, being the first part spun by the animal, is of poor quality, and is termed *floss silk*. This floss-silk covering is taken off, and exposes the hard cocoon of one continuous thread of fine silk below. The method by which this thread is taken off is known as *reeling*. The silk differs considerably in quality, and the cultivators sort the cocoons, accordingly, into distinct lots, being guided by the observation of colour and other circumstances. The cocoons being prepared and assorted, the material is ready for being reeled. The great point in reeling is to make the thread of as even a thickness as possible: *perfect equality* is scarcely attainable. An experienced reeler, with the assistance of a girl to turn the wheel, can with ease wind off a pound of silk in a day.

A number of cocoons are placed in a dish of warm water, in order to dissolve the gummy fluid already mentioned, and allow the thread to be taken off. The reeler uses a whisk of fine twigs to take up the loose points, which she passes in sets of about five through the eyes of the machine. These compound filaments, after being made to cross and rub on each other so as to clean their surfaces, are combined first two and two, and finally all together into a single thread, which is wound upon a reel or frame, and formed into hanks and skeins.

Raw silk, preparatory to weaving, must be made to take one of three forms—respectively termed *singles*, *tram*, or *organzine*. *Singles* is merely the raw silk twisted, in order to give more firmness to its texture. All raw silk, for whatever manufacture designed, must undergo this process. *Tram* is formed by twisting together, not very closely, two or more threads of raw silk, and this generally forms the weft, or transverse threads of the web. *Organzine*, which is principally used for warp, is produced by a very elaborate process, of which it would be impossible to convey any correct

idea to the general reader without the aid of a diagram. The principle of the process, however, may be generally stated to be like that of making rope, where the combined strands are twisted in an opposite direction to that given to the separate threads, and this is accomplished by giving a reverse motion to the machinery; whereas singles and trams are twisted only in one direction, similarly to twine, or to the individual strands of which the larger rope is made. Silk thread intended for organzine is in the first process twisted in a left-hand direction.

We now proceed to describe the processes by which silk is prepared for weaving purposes. As the mechanism employed for effecting these processes is very similar in principle to that of the 'cotton' machinery, the reader will do well to consult the illustrations of the latter while perusing the following description. This remark applies also to the section on WOOL.

The first to be noticed is that of *winding*. In this operation, the hanks are stretched on a light hexagonal reel, termed a swift. The silk is led from these to a series of bobbins placed horizontally in a frame, some distance above, and in advance of the reels, one bobbin being allotted to each reel. The threads of silk are wound upon the bobbins, uniformly over the surfaces, by being passed through eyes which are placed on a bar having a lateral movement to and fro. The silk thread thus wound upon a series of bobbins is next cleaned—that is, each thread is made to pass through an aperture which is just of sufficient size to allow it to pass through alone, but which detains all extraneous matter: before passing through the hole, the silk is cleaned from dust by coming in contact with a brush.

The next operation is that of *throwing* or twisting, which is effected by spinning-machines, although, correctly speaking, the process is not one of spinning, which involves the presence of short fibres to be operated upon. The silk bobbins from the previous machine are placed horizontally in a frame in one or two rows, one above the other; at a little distance below these horizontal bobbins are placed a series of vertical ones; these, however, have no motion on their axes, like the horizontal ones, but are stationary. A spindle passes through a central aperture on each of the bobbins, and is made to revolve quickly. At the upper end of the spindle, a small flyer (see Cotton) is fixed. The silk is passed from the horizontal bobbin through the eye of the flyer, and by the rapid rotation of the latter round the vertical bobbin, it is wound upon its surface, receiving at the same time a twist. The amount of twist given to the thread is dependent upon the difference of speed between the flyer and the horizontal bobbin which gives out the silk.

In the manufacture of tram, sewing-silk, and organzine, the next process after spinning is that of *doubling*. The bobbins, equal in number to the threads to be united, are set in a frame, the loose ends of the silk of the bobbins are collected and passed through a loop, and finally wound round a horizontal reel. This is placed in the throwing-machine, and the ends carried through the eye of a flyer, which, by its rapid rotation round a bobbin, winds it upon its surface, giving it at the same time the desired twist. A number of bobbins and flyers are arranged in one machine, and an apparatus attached by which, when a thread breaks, the flyer with which it is connected is stopped.

The organzine, when finished, is transferred to reels instead of bobbins, whence it is made up into skeins, and sorted for sale or use. Previously to this, however, the reels are subjected to a process of steaming for two or three minutes, in order to prevent any 'after-crinkling.' The silk thus thrown is called hard silk, and must be boiled for some hours, with a quantity of soap, in order to discharge the gum, and thereafter well washed in a current of clear water, to discharge the soap, after which the silk appears soft and glossy. Besides these varieties, there is another called *sewings*, which are compound threads of silk, wound, cleaned, doubled, and thrown, with especial reference to their ultimate use for sewing. *Marabout* is a peculiar kind of thrown silk, generally formed of three threads of raw silk; and being white as it comes from the cocoon, it takes the most delicate shades of colour at once without the discharge of its gum.

Silk is woven into various fabrics, plain silk being produced by the ordinary loom, and figured by the Jacquard-loom. The fine soft pile of *velvet* is produced during the process of weaving, by inserting short pieces of thread doubled under the shoot or weft, and which stand upright in such a way, and so close together, as entirely to conceal the interlacings of the warp and shoot. In the production of every yard of velvet, six yards of pile at least are used. The loops of the doubled threads intended for the pile are supported by grooved wires, and the loops are afterwards divided by running a sharp instrument, called a *treval*, along the groove. This is done by the hand, and of course requires great dexterity, as the slightest deviation from the proper line would infallibly injure, if not wholly destroy, the silk. It is considered a good day's work for one man to weave one yard of plain velvet, for which he is paid about five times as much as for weaving plain silks.

The refuse of the throwing, and the silk known as floss, are spun by a series of processes analogous to those of the cotton manufacture into yarn, which is used for the manufacture of the cheaper kinds of silken materials. The first process in the *spinning* of silk, properly so called, is the disentangling of the short fibres by a species of hackling, and thereafter parallelising them by a machine called the filling-engine. Next passed through the drawing-engine, the silk is freed from all impurities and extraneous matter by being combed. Cut into short lengths, the silk is then scutched, by which it is converted into a species of fine down. The gum is at this stage removed from it by boiling it in water, and thereafter cleaning it in pure water. Subjected to strong pressure, and dried, it is again scutched, and finally converted into yarn by operations closely resembling those of the cotton manufacture.

In Britain, the annual value of the silk manufacture is estimated at nearly ten millions sterling—more than nine-tenths of which are for home consumption. We draw our chief supplies of the raw material from Bengal; from Italy, which produces about eleven million pounds annually; from China, where, next to tea, it is the staple article of export; from Turkey; and in smaller quantities from Holland, the United States, and other countries. The foreign states in which the manufacture chiefly exists are China, India, Italy, Switzerland, and France. It has been estimated that a million and a half of human beings derive their sole support from the culture and manufacture of silk, and that it creates an annual circulating medium of between thirty and forty millions sterling!

In 1850, the number of silk-factories in England and Scotland (Ireland possessing none) was 277, using 2858 horse-power in steam, and in water 853; the number of spindles was 1,225,560, and of power-looms 6092; and the number of hands employed, 29,877 females, and 12,667 males.

WOOLLEN.

Wool, according to the definition given by Professor Owen, 'is a peculiar modification of hair, characterised by fine transverse or oblique lines from 2000 to 4000 in the extent of an inch, indicative of a minutely imbricated scaly surface when viewed under the microscope, on which and on its curved or twisted form depends its remarkable felting property, and its consequent value in manufactures.' Wool, although principally derived from the sheep in its many varieties, is obtainable also from the goat and other animals. The Tibet goat

furnishes the finest of all wool, the merino sheep the next best.

Wool, as used in our manufactures, is divided into two sorts—the long, or combing, and the short, or carding wool. These, again, give rise to the two grand divisions of the trade—the cloth, or the short-wool, and the worsted, or long-wool departments. It is our duty to explain briefly the various processes gone through in these, taking the cloth as first in order.

On arrival at the factory, the various qualities of wool are sorted, three classes—*primes*, *seconds*, and *thirds*—being the gradations generally used. To free the wool from the animal grease, and enable it to take on the dye, it is *scoured*. The dyeing either takes place at this stage or is deferred till the cloth is woven: when the latter is the case, it is termed *piece*, when the former, *wool* dyed.

The wool is now subjected to the action of the *willy*—much resembling in arrangement and operation the machine of like name in the cotton manufacture. The wool is opened up and projected from the machine in a loose open condition. It is afterwards picked, to free it from all burrs and extraneous matter, and to separate the locks which differ in colour. A machine has been recently introduced, named the burring-machine, which effectually frees the wool from all burrs, &c. Previous to passing through this machine, the wool is well oiled, to render its working more easy. If the burring-machine is not used, the wool, after being picked by hand, is oiled, and passed through the willy a second time. After this is done, it is passed to the scribbling-machine, which is very similar to the breaker carding-engine used for cotton. In the carding-engine, the next machine in sequence, the card-teeth are placed in the main cylinder in the form of narrow strips. The wool is thus passed from the machine in the form of long narrow bands. Each band, as it issues from the machine, passes between a fluted roller and a semicircular case which embraces it; by which means it is rubbed round into the shape of hollow tubes, equal in length to the breadth of the band of wool from which they are cut. The tubes of wool, termed cardings, are next passed to the 'slubbing billy,' the operation of which is similar to that of the cotton roving-machine. The rolls, or tubes of wool, are placed lengthways on a sloping board in front of the machine, and are taken up by the drawing-rollers. The tubes of wool being all of a determinate length, it is necessary to add new lengths to the ends of those passing through the rollers, in order to maintain the continuity of the sliver of wool. To maintain the supply is the duty of the little attendants called 'pieceners.' The wool is finally wound upon the bobbins or spindles, ready for the mule, where it is spun into yarn for weaving. The three preliminary processes are thus seen to be scribbling, carding, and slubbing. By means of a machine known as Mason's (of Rochdale) condenser, introduced a few years ago, and now being rapidly extended in use, a vast deal of labour is saved in the way of 'piecening,' and the three operations of feeding, piecing, and slubbing are effected by one machine. Its operation may be briefly described as follows:—The sheets of wool from the scribbling-engine are wound round rollers; the web of wool thus obtained is laid on the feed-cloth of the condenser, and supplied continuously to a revolving tube, which imparts to it a certain degree of false twist; passing through another tube, it is wound upon a drum, making a continuous sliver, sixteen inches diameter, and four or five inches wide. A number of these narrow laps are placed side by side on rods in front of the machine; the laps from each are passed to the carding-engine, which delivers the wool at the other side in the form of endless bands, which are removed from the main carding-cylinder by doffers. From these the wool is taken by stripping-rollers, and made to pass between double endless twisting straps, which impart to the slivers an amount of false twist. They are finally delivered to bobbins, which are then ready to supply a continuous sliver to the spinning-mule—a machine very similar to the cotton-mule.

The yarn prepared by the mule is then woven into cloth, and ready to be put through the succeeding operations, as follows:—The oily matter is removed from the cloth by scouring, in order to restore the roughness to the fibres, preparatory to the subsequent process of milling. In articles made of long wool, the texture is complete when the stuff issues from the loom. The pieces are subsequently dyed, and a gloss is communicated to them by passing them between heated metallic surfaces. But in cloths made of short wool, which is generally dyed before being spun, the weaving cannot be said to complete the texture. When the web is taken from the loom, it is too loose and open, and consequently requires to undergo another operation, called *fulling* or *milling*. This is performed by a fulling-mill, in which the cloth, being first freed from its oil by the use of fuller's-earth and other detergents, is immersed in water, and subjected to repeated compressions by the action of large beaters, formed of wood, which repeatedly change the position of the cloth, and cause the fibres to felt, and combine more closely together. By this process, the cloth is reduced in its dimensions, and the beauty and stability of the texture materially improved.

The process of milling is now rendered much more speedy and economical by the use of the fulling-machine, which does the same amount of work at a less expense of detergent material. In this machine, the cloth is fastened together so as to form an endless rope, as it were, and subjected to the action of weighted rollers, which press it against the sides of the trough or case in which they work; soap is passed to the cloth through doors made in the machine for this purpose.

This tendency to become thickened by fulling, is peculiar to wool and hair, and does not exist in the fibres of cotton or flax. It depends on the fibres or hairs being barbed or serrated, so as to admit of motion in one direction, but not in another. There thus results an entanglement of the fibres, which serves to shorten and thicken the woven fabric.

The nap, or downy surface of broadcloths, is raised by a process which, while it improves the appearance, tends somewhat to diminish the strength of the texture. It is produced by carding the cloth with the barbed or hooked fruit-cone of the common teasel (*Dipsacus fullonum*), which is cultivated in England for the purpose. This operation extricates a portion of the wool, and lays it in a parallel direction on the right surface of the fabric. Teaseling was at one time performed by hand, a number of the heads being placed in a small frame; machinery is now employed, the teasels being arranged on a revolving cylinder, with which the cloth is made to pass in contact in a direction contrary to that of its revolution. The nap thus formed is then cut off to an even surface by the process of *shearing*. This is performed in various ways; but in one of the most common methods, a large spiral blade revolves rapidly in contact with another blade, while the cloth is stretched over a bed or support, just near enough for the projecting filaments to be cut off at a uniform length, while the main texture remains uninjured.

The cloth is finally prepared for market by a series of finishing processes, as hot-pressing, boiling, and steaming. In the former, the cloth is subjected to enormous pressure between hot plates. Boiling consists of immersing the cloth, tightly wound upon a roller, in warm water, after which it is dried in a hot room while tightly stretched out. In steaming, the cloth is wound upon perforated rollers, into which steam is admitted. After all this, it is closely examined, to take out all unevennesses, and to make up any minute holes in the fabric;

and, finally, it is cold-pressed, and made up into bales, when it is ready for the market.

The second branch of the woollen trade is the worsted or long-wool manufacture. The principal operations in this department being analogous to those of the cotton manufacture, a very brief glance at their nature and sequence is all that is necessary.

The wool is first washed and cleansed, much of the moisture being pressed out after this operation by passing it between rollers. The wool is next dried, and afterwards passed through a species of willow, which opens, cleanses, and straightens the fibres, which are now ready for combing. This is a very unhealthy and tedious process, being carried on in hot rooms. The process consists in placing wool fibres on a comb, evenly laid and firmly fixed between the teeth, and passing the teeth of a second comb through the mass. The teeth of the combs are heated in a stove, so as to render the wool soft and pliant. Each comb has three rows of teeth of different heights: a portion of the wool is left, called noyl, which the comb will not straighten; this is used for coarse yarn. Machines have been introduced to supersede this process, but with indifferent success.

In place of combing, the wool is sometimes straightened and the fibres parallelised by the use of the carding-engine. The slivers of wool, prepared either by combing or carding, are drawn and spun into yarn by machines closely resembling those used for similar purposes in the cotton-trade.

The classification of worsted stuffs is as follows:—1. Fabrics composed entirely of wool; 2. Of wool and cotton; 3. Wool and silk; 4. Wool, silk, and cotton; 5. Of alpaca and mohair, mixed with cotton or silk. 'The first of these divisions comprises the well-known fabrics called merinoes double twilled, so denominated from the Spanish wool of which they were first manufactured. (Bradford produces goods of this class little inferior to the French merinoes.) In single-twilled merinoes, the worsted manufactures of Yorkshire have at all times had the decided precedence. Shalloons, says, serges, lustrings—all stout and heavy articles—are manufactured chiefly at Halifax and Keighley. Damasks for curtains and hangings are also made at Halifax, and this branch of the trade has arrived at great perfection, both in excellence of material and elegance of design. Of the fabrics composed of wool and cotton, the articles denominated Cobourg and Orleans cloth—the former being twilled, and the latter plain—have been staple manufactures, of which the consumption has been immense; they are made chiefly at Bradford and Keighley. Many of the silk-warp and worsted-weft fabrics are distinguished by their richness and durability. The alpaca and mohair manufactures—carried on at Bradford and Bingley—are remarkable for their softness and brilliancy, and the great variety of purposes to which they are applicable. The importation of alpaca wool has increased from 7000 bales in 1836, to 20,000 in 1850; and of mohair, from 5621 bales in 1841, to 12,884 bales in 1850. It is in the production of articles in which wool of various kinds is combined with cotton and silk, that the superiority of the British manufacturer is most apparent, no such goods being produced on the continent to any extent or of any great excellence. The consumption of these various manufactures is immense; the looms are capable of producing upwards of 80,000 pieces per week, averaging thirty yards each.'—(Jury Report of Great Exhibition, 1851.)

Woollen fabrics, manufactured as above, are generally known by the name of *cloths*, of which there are several varieties in common use, as broad, narrow, and habit cloths, all of which are worked plain, and only differ in width or in quality. When twilled, they are termed *kerseymeres*, *kerseymerettes*, *pelisse-cloths*, &c.; and when peculiarly finished—as, for example, with long, tufted, or velvet naps—they are known by such designations as *dreadnought*, *frieze*, *swanskin*, *plush*, and *duffel*. *Tweed* is a light structure, now largely used for trousering; *flannels*, of whatever variety, are all loosely woven; *baize* is a kind of flannel with a tufted nap; and *blankets*, of which there are many varieties manufactured in different parts of the country, are also loosely woven and finished with a long nap raised by rollers covered with brass pins. Besides the manufacture of cloths, blankets, and flannels, the department of woollen fabrics comprehends *carpets* and *hosiery*, two very distinct but important branches. Three kinds of carpets are usually made—Venetian, Kidderminster, and Brussels. Venetian carpeting is a plain fabric, composed of thick linen woof on a woollen warp, and is employed chiefly for stair or lobby coverings. The Kidderminster carpeting is by far the most common; it consists of two woollen webs, woven together, and intersecting each other at particular parts, so as to produce definite figures of different colours. The manufacture of this species of carpets has been long carried on with advantage in different parts of Scotland. Brussels carpets possess a basis of strong linen threads, on which the pattern in woollen is thrown up in loops, which are kept firm by small rods. When the web is woven, the rods are pulled out, leaving a soft surface of the closed ends of loops. Latterly, a great improvement has been made in Brussels carpet-weaving, which has also been adopted for shawls. Instead of using threads of one particular colour throughout, and throwing up the threads as they were required to form the pattern, the custom is now to dye different parts of the same thread with different colours, suitable to the pattern required. Thus a single thread may be dyed in patches of red, yellow, black, or any other colour, and it performs its part in the pattern through its entire length; the saving of material by this ingenious mode of dyeing is immense.

In 1850, the number of factories engaged in the *woollen* manufacture in the United Kingdom was 1497—of which England had 1306, Ireland 9, and Scotland 182. The number of horse-power in steam in the 1497 factories was 13,455, in water, 8769—giving motion to 1,595,278 spindles and 9439 looms.

The number of factories in the same year in the United Kingdom employed in the *worsted* manufactures was 501—of which England had 493, Ireland 2, and Scotland 6. The amount of horse-power in steam was 9890, in water, 1525—giving motion to 875,830 spindles and 32,617 power-looms. The hands employed were 27,337 males and 53,877 females.

Of the process of *weaving* by hand—an operation common to all the textile manufactures we have been describing—we now propose to give a brief description. A certain number of threads arranged alongside of, and parallel to each other, constitute the *warp*. This is evenly wound on the beam, *a*, fig. 20, of a loom, and is thence extended to another beam, *b*, at the opposite end.

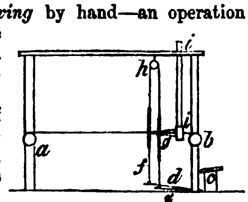

Fig. 20.

Between the beams are suspended two 'healds,' or 'heddles,' seen edgewise at *f*, *g*, fig. 20. A front view of one is presented in fig. 21, where *g*, *h* are two bars, between which cords are stretched, each having a loop, *f*, in the middle. The threads of the warp are drawn through these loops, a thread passing through a loop in each heald alternately. The healds are united by a cord which passes over a pulley, *h*, fig. 20. The bottom bars of the healds, *f*, *g*, are connected to 'treddles,' *d*, *e*; by pressing an end of which alternately, the weaver sitting on *c* can raise and depress *f* and *g*. The threads

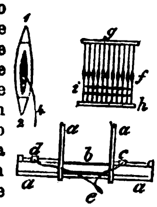

Fig. 21.

of the warp, after passing through the loops of the healds, are taken through the openings or 'dents' of the reed, *b*, fig. 21, attached to the batten or lay, *aa*, which swings to and fro on the frame, as at *ii*, fig. 20. The rising and falling of the healds cause one set of the threads to be raised and the other depressed, so as to cross each other, and make an opening, or 'shed,' as it is termed, from one side of the warp to the other. Every time that the threads are opened, a shuttle, containing the *woof* or *weft*, is thrown across from one side of the warp to the other, and the thread of woof thus left is driven home by a lay, or properly by a comb-like process of reeds called a *dent*, which the lay brings forward. A reversal of the warp makes another opening, which is similarly crossed by the shuttle, and so on, each cast of the shuttle adding to the woven fabric by the breadth of a thread. Plain cloth of all descriptions is formed by this simple species of operation, whether the loom be driven by hand or by steam power.

The shuttle is formed of hard wood, and shaped like a canoe; it is hollowed out in the middle, to afford space for the cop to lie in; the thread of which is brought through a hole in the side. Small wheels are sometimes provided to the shuttle, to enable it to run easily in the 'race.' The shuttle is driven through by what is called a 'fly' and 'picker.' Two pieces of wood, *c*, *d*, fig. 21, known by the latter name, move along a wire, and are connected by a cord, to which a handle, *e*, is attached; by jerking this from side to side, the pickers send through the shuttle with great force.

The only changes of pattern which can be readily produced by plain weaving are stripes or checks—the former generally depending upon the colours of the warp, and the latter upon the colours of both warp and weft. Thus stripes in the direction of the cloth may be produced by using warp of various colours, or a warp composed of threads of different sizes and substances; stripes across the web may be formed by using shuttles containing various colours and substances; checkered patterns, by varying both warp and weft; and figures, to a certain extent, by raising and depressing alternately certain portions of the warp. *Twills* are formed by causing the thread of the weft to pass alternately over four and one of the threads of the warp, and performing the reverse in its return. Plain twilling is adopted in various linen fabrics—in silk, it is called satin; in cotton, fustian or jean; and in woollen, serge or kerseymere. In ornamental or *figure* weaving, an expensive, or at least complex, harness is required, the warp being of various depths, several sets of heddles being also in requisition, and it may be a number of shuttles, each having its own system of thread or threads. It is easy to see how, by these means, a great variety of figures may be produced; and in order that the weaver may clearly understand the intended texture of his piece, all the threads are drawn on cards before he begins, in a manner peculiar to themselves; and these he reads as he proceeds, just as a musician plays from his sheet of music. Looms of this kind, whether for linen, silk, cotton, or carpet fabrics, are known as draw-looms, the most perfect of which is that invented by M. Jacquard, a practical weaver at Lyon. With modifications adapted to the object in view, the Jacquard-loom has now superseded all others for figure-weaving—the skill and labour required to work it being little more than that necessary for plain weaving.

FELT—HATS—STRAW-PLAIT.

Felting is the process by which different kinds of hair, fur, or wool are blended into a compact texture, without undergoing either spinning or weaving. It depends upon the serrated structure of the fibre—a structure which has already been noticed under milling, and which may readily be observed by passing a hair through the fingers in opposite directions. This peculiar structure allows the fibres to glide amongst each other, but only in one direction; so that when the mass is agitated, the root end of each fibre is pushed forward among the rest, but cannot be retracted, which serves to entangle and contract the whole together. Vegetable fibre, being of a smooth linear texture throughout, cannot be felted; and among animal fibres, those are best adapted for the process which are naturally curled or wavy, and have the deepest serratures. Felting is best seen in the making of beaver or stuff hats, to which we shall shortly advert.

The materials commonly used for hat-making are the furs of the beaver, seal, hare, and rabbit, and the wool of the sheep. The furs of most animals are mixed with a longer kind of hair, from which they have first to be separated; they are then cut off with a knife, and sorted by a blowing-machine, which carries the lightest and finest fibres to the extremity of a hollow trunk or funnel, while the heavier and coarser are left at proportionate distances from the fanners, or source of the current. The materials to be felted are next intimately mixed by the operation of *bowing*, which depends on the vibrations of an elastic string; the rapid alternations of its motion being peculiarly well adapted to remove all irregular knots and adhesions among the fibres, and to dispose them in a very light and uniform arrangement. This texture, when pressed under cloths and leather, readily unites into a mass of some firmness. A piece sufficient to form a hat is next taken up, and dipped in warm water, containing a little sulphuric acid, and moulded into a large conical shape, which is afterwards reduced in its dimensions by working it several hours with the hand, for the purpose of further thickening and fulling it. At this stage any knots are removed, and fresh felt here and there added; the hat is then shaped, water-proofed by a lac varnish, tied upon a block, dyed, stiffened by the application of a solution of glue, steamed, brushed, and ironed. The brim is then trimmed, and it is ready for lining and binding. The material felted as above described generally consists of a variety of furs, as those of the hare, rabbit, and beaver, lamb's-wool, goat and camel's hair, cotton, and silk. Most manufacturers make what they term a foundation of coarser material, to which they apply beaver or other fine furs as a *plate* or finish. What are called *beaver* hats are thus completed with the fur of that animal; while in *stuff* hats this fur is altogether omitted. *Silk* hats have a foundation of felt, chip, straw-plait, whalebone, or pasteboard, upon which silk-plush is afterwards applied. From their cheapness, durability of colour, and lustre, they have lately come much into use, though scarcely so durable, or so soft and elastic for the head, as the old beaver. The best variety of the silk hat is that in which a fine Paris plush is fixed upon a beaver body. *Gossamer* hats, for summer wear, are those in which the foundation or body is of willow-chip or other light material, with a plush of floss-silk.

Felt cloth, manufactured much in the same manner as felt for hats, is a fabric employed for several economical purposes. At one time, it excited considerable expectation as a substitute for woven woollen-cloths, and perfect imitations of these were produced, but they were found deficient in firmness and durability. More recently, a pneumatic process of felting was introduced, of which better hopes are entertained. The mode is as follows:—Into an air-tight chamber is put a quantity of flocculent particles of wool, which, by a kind of winnowing wheel, are kept floating equally; on one side of the chamber is a net-work, or gauze of metal, communicating with another chamber, from which the air can be abstracted by an exhausting syringe or air-pump; and on the communications between the chambers being opened, the air rushes with great force to supply the partial vacuum in the exhausted chamber, carrying the flocculent particles against the netting, and so interlacing the fibres, that a cloth of beautiful fabric

and close texture is instantaneously made. The only objection to cloth of this kind was its rawness, or liability to shrink after being wetted; and for this reason, we believe, it has never come into anything like use for clothing. Coarse feltings, variously treated, are used for roofing, underlaying copper-sheathing, and other analogous purposes; and for these ends their cheapness renders them specially available; but where elegance and durability are sought to be combined, as in dress and household furnishings, woven fabrics must ever take the precedence.

Straw, plaited, or otherwise worked into a fabric, is in use in almost every country as a material for a light and ornamental head-dress. Many of the tropical grasses are eminently fitted for this species of manufacture, and thus navigators often bring from the Indian Archipelago and South-sea Islands hats, fans, baskets, and other articles, exhibiting a beauty of texture and intricacy of design which the most expert straw-plaiter in Europe could scarcely surpass. It is to straw-plaiting as a branch of civilised industry, however, that we would now direct attention; and for this purpose present the following abridged exposition from the *Encyclopædia of Domestic Economy*:—*Dunstable* hats are made of whole straw, plaited in long narrow stripes or ribbons, which are afterwards sewed together in the form of a hat or bonnet. The weight and clumsy appearance of these bonnets first suggested the idea of splitting the straw into stripes; but it was a considerable time before a method was invented of performing this in a perfect manner. *Split-straw* is an elegant manufacture, brought into use about forty years ago, and has now become very general for women's bonnets. The straw of wheat or of rye is cut at the joints; and the outer skin being removed, it is sorted into small bundles, and is next split by means of a very simple instrument, and delivered to be plaited. The plait is sold by the score yards, and about three score and a half will make an ordinary-sized bonnet. It is sewed by the bonnet-makers, and then blocked, which is a laborious process; and after being pressed, wired, and lined, is ready for sale. There are markets in the plait districts for the sale of straw, plait, and bonnets; the best market for the latter is St Alban's. Straw is bleached, and straw-hats cleaned, by putting them into a cask into which a few brimstone matches are placed lighted. The fumes of the sulphur have the effect of destroying the colour and whitening the straw. The same effect may be produced by dipping the straw into chloride of lime (common bleaching-powder), dissolved in water, an article which may now be procured at any large chemist's. Of straw-hats, the *Leghorn* are the most highly prized, as the finest in the world; they are made in the neighbourhood of Florence, Pisa, the district of Siena, and the upper part of the vale of the Arno, and are exported from Leghorn. The straw is produced from a small kind of wheat, cultivated on a poor soil, and bleached like flax; it is remarkable for its strength and whiteness; the plait is extremely regular, and the straw is not split. Attempts have been made to grow this kind of wheat in England; but hitherto without success. About twenty years ago a firm established straw-plaiting in the Orkney Isles, and adopted rye-straw as the material. At first, there seemed some prospect of success; but it does not appear that the competition of foreign-grown straw could be successfully met. Various other materials besides straw are used for making light hats. *Chip*, which is thin strips of wood made by a plane, is employed; the *willow* is found to answer well, and these strips are woven with a loom into a kind of twill or diamond tissue, and afterwards bleached like straw.

PAPER.

The earliest kind of paper, or material for writing on, of which we have any account, was the *papyrus*, used by the ancient Egyptians; and hence our modern word *paper*. The papyrus was a plant, from which thin fibrous membranes were stripped, and the membranes being pressed together, formed small sheets of a rude kind. The Chinese are said to have understood the art of making paper from the pulp of rags in very early times; but whether the European mode of making paper was derived from that quarter, is not clearly known. The art was introduced amid the obscurities of the middle ages, and most likely through the ingenuity of the Arabians. In the beginning of the fourteenth century, a paper-mill was established at Nuremberg in Germany; and in 1588, a mill was erected at Dartmouth in England. Little progress was made, however, in the manufacture of paper in this country before 1770, when the first mill for fine paper was established at Maidstone by the celebrated J. Whatman. The previous supply had been derived principally from France and Holland.

The principle on which paper is made is very simple: a portion of linen cloth is ground to pulp; this pulp is shaken in a fine wire-sieve, so as to settle in a thin cake, or sheet; the sheet is pressed, in order to squeeze out the liquid; and when dry, we have a sheet of paper. Instead of new linen cloth, rags, for the sake of economy, are always employed; and the more substantial the rag, the stronger in texture is the paper. The quantity of rags produced in Great Britain and Ireland being altogether insufficient to supply the demand for paper, large importations take place from continental Europe, chiefly Germany. Cotton rags, and the refuse cotton of factories, are also employed in the paper manufacture; but only for inferior sorts, or as an alloy, which is not always justifiable.

Any vegetable fibre, indeed, may be used in the fabrication of paper; and straw is much employed in the manufacture of the commoner kinds. A recent patent proposes to make paper from stone.

The great proportion of paper in use is made by machine, very little indeed being made by the old hand-process; to a description of machine-made paper we shall therefore confine ourselves.

Preparation of the Rags.

After the rags arrive at the mill, they are picked and sorted into four or five qualities. All substances not suited for paper-making, or which might injure the machinery—such as pins, buttons, pieces of silk, and woollen cloth, must be carefully removed. The rags are then cut up into pieces about four inches square, by bringing them up against the standing edge of a fixed knife. After being cut, they are well agitated in a cylinder, which frees them from particles of dust. The rags are then boiled in an alkaline lye composed of from four to ten pounds of the carbonate of soda to the hundredweight of rags, according to their quality, and a third part additional of quicklime, to render it caustic.

After being boiled, the rags are carried to the first washing-engine, which consists of a large oblong stone trough, into which a stream of water is allowed to flow, and to escape by the other end. This cleans the rags most effectually, the run of water carrying away any impurities that may still adhere to them. On one side of this trough is an engine, which again washes and grinds the rags, and is termed by the workmen the *breaking-in machine*. This powerful apparatus consists of an elliptical-shaped trough, made generally of wood, lined with lead or copper; within it, a grooved roller revolves horizontally over the surface of a sharply grooved plate, by which the rags are torn to shreds. The grooves on the roller, and those on the plate, act upon the pieces of rags much in the same manner as cutting with a pair of scissors. The trough is half-filled with water, which comes in at one end, and escapes through holes at another part. The operation of *grinding*, as it is called, occupies about an hour and a half; and when the rags are sufficiently reduced to a pulp, the stuff is passed down from the trough to the draining-boxes. On reaching

the draining-boxes, the water is allowed to run off from the pulp previous to the bleaching-process. The common method of bleaching is to steep the pulp in a solution of chloride of lime, by which the fibres are not so much injured as when chlorine is used. In bleaching, great care should be taken that the solution is not too powerful, or the texture of the paper may be materially injured by the process.

After bleaching, the pulp is again put into a washing-machine, to free it thoroughly from the bleaching-liquor. This process is similar to that previously described, except that the roller is screwed down closer to the fluted plate, so as to reduce the pulp to a finer consistence. In making what is called machine-paper, the size is now added, the addition or the want of which constitutes the chief difference between paper for the reception of ink and the other sorts. The kinds of size principally used consist of either white soap, starch, glue, or dissolved rosin, with the addition of a few pounds of alum. The size is strained through a sieve into the beating-engine, and there mixed with the pulp.

From the second washing or beating machine, the pulp is passed down to a large tun or vat, called the *stuff-chest*, which is merely a reservoir to keep the pulp till it is put into the machine which converts it into paper. This vat is furnished with agitators at the bottom, to keep the pulp of an equal thickness, which now bears a strong resemblance to curdled milk. Previous to its being put into the vat, however, it is now almost universally the practice to strain the pulp through bars of brass. These are planed perfectly smooth at the edges, and placed so closely together, that the fibrous part of the matter must pass through longitudinally. By this means, knots, &c., are kept out, which formerly cost considerable trouble to scrape from the surface of the finished paper. This strainer was the invention of Mr Ibbetson of Poyle, to whose ingenious contrivances the paper manufacture is greatly indebted.

From the vat or stuff-chest, the pulp, prepared as already described, is let out by a sluice into a pipe, which leads it to one end of the *making-machine*. The opening from this corresponds exactly with the breadth of the machine; and the quantity and thickness of the stuff admitted into the latter are regulated according to the kind of paper to be made.

The machine now in general use for the making of paper is the invention of Louis Robert, a Frenchman, and was brought to this country about sixty years ago by a M. Didot, who, with the assistance of M. M. Fourdrinier, and Mr Donkin, the engineer, greatly improved the invention, and obtained a patent for it.

The first part of the machinery upon which the pulp comes is a brass wire-cloth, which is woven in the same way as linen, and is of so fine a texture that there are seventy wires in the inch. This wire-cloth may be described as a sort of belt without any break, which is kept continually revolving, but in such a way that the upper side, upon which the stuff is received, preserves a flat and horizontal surface. The wire-cloth moves upon a number of small copper-rollers, which have an agitating horizontal motion, and this distributes the stuff equally over the cloth, giving a uniform strength and thickness to the paper. After passing between a pair of rollers, where it delivers the stuff, it is led backwards again under the frame; and so goes on in a continuous revolution. Movable sides are attached to the upper surface of the wire, which regulate the breadth of the sheet to be manufactured.

The first pair of rollers through which the stuff passes are called the couching-rollers. The under roller is simply cast iron, while the upper one is covered with woollen cloth of a peculiar texture, manufactured for the purpose. It is upon this upper one that the stuff is delivered. The pressure from these rollers is slight; and the pulp is next led on to an endless felt, and passes between two cast-iron rollers. The machinery of this felt must be so regulated that it will go with the same speed as the wire-cloth and couching-rollers, otherwise confusion would ensue. In passing through the first pair of rollers, only one side of the stuff is rendered smooth; but in the second pair it is reversed, and the rough side is now pressed. These rollers are closer than the first pair, and the pressure being greater, the sheet is now more dry and firm.

The sheet next passes through two other pair of rollers, which press out the water, and render the paper smooth and firm. It is then carried to the drying-cylinders, which are hollow, and filled with steam, introduced by pipes placed at both ends of their axes. The paper is again passed through a pair of rollers, to smooth it after being dried, and is then wound upon a reel. As one reel is filled, it is taken off, and another put on in its place; and it is evident that the paper can be made of any length the reel is large enough to hold.

The whole machinery upon which the process we have described is performed, is about fourteen feet in length, and moves at the rate of from twenty-five to forty feet per minute. At one end is seen running in a stream of liquid resembling curdled milk, and at the other comes out a finished fabric, the time required for manufacturing thirty feet of which is little more than a minute. Near the extremity of the machine is usually placed an apparatus for receiving the reels of paper in web, and drawing out and cutting the web into sheets according to the regulated size. The sheets are then sorted and packed up in the usual manner.

By the operations now described, all the printing-papers, and also letter-papers of an ordinary kind, are now made, and that to an immense extent.

In 1851, there were 413 machines at work in the United Kingdom; and the annual value of the paper manufactured is stated to be two millions sterling.

CAOUTCHOUC—GUTTA-PERCHA.

These two remarkable substances, to which we have briefly adverted in previous numbers, are now so largely used in connection with textile fabrics, that a more extended notice of their properties and applications may not be uninstructive to the reader.

Caoutchouc was first seen in Europe about the middle of the eighteenth century. It was then brought from Guiana, and other provinces on the eastern coast of South America, and, from its valuable power of cleaning paper, was called *India-rubber*. It is the produce of several tropical trees, particularly *Ficus elastica*, *Jatropha elastica*, and *Urceola elastica*. It may also be obtained from the juices of others belonging to the same natural order; but our commercial supplies, which now amount to several hundred tons yearly, are mainly derived from the *Ficus elastica* in the old world, and from the *Jatropha* in the new. The mode of obtaining it is simple:—In the cooler seasons of the year, incisions are made around the tree, completely through the bark, and the milky juice which exudes is either immediately applied to moulds of unburnt clay, or collected in vessels. If applied to moulds, it is dried, layer by layer, over a wood-fire, till of the desired thickness; if otherwise, it is allowed to coagulate and harden at leisure. Caoutchouc in the solid state is highly elastic, is insoluble in any of the ordinary solvents, melts at 248° Fahrenheit, and remains viscid for a considerable time, is highly inflammable, burns with a white flame and much smoke, emitting at the same time a peculiar and offensive odour. When solid, it may be cut into threads and sheets of great tenuity and thinness; when melted, it may be used as a lute or cement; and when dissolved in naphtha, which is the most common solvent, it may be employed as a varnish, and applied to the surface of any textile fabric, rendering it quite impervious to air or moisture. The applications of caoutchouc to useful purposes are very numerous; with many of these our readers are doubtless acquainted; and every year sees acquisitions

to their number. In the short space at our disposal, we can only notice the most remarkable.

The water-proof garments well known by the name of Mackintoshes—from the name of the inventor—are formed of fabrics covered on one side with the caoutchouc; or two fabrics are joined by a thin layer between them. To obtain the material in the thin sheet required, it is dissolved, or rather, under the improved process, it is kneaded with powerful machinery, along with the spirit of turpentine or naphtha, until it is thoroughly softened without being liquefied; it is then spread upon the cloth by means of a flattening mill. The cloth thus made has, however, the peculiar property of becoming stiff and rigid in cold weather. This property of caoutchouc has been taken advantage of in the manufacture of garters and other materials formed of elastic threads. The caoutchouc is cut by ingenious machinery into long bands; these are raised in temperature, stretched out to form long threads of small diameter, and wound upon bobbins. The threads are next covered with silk or cotton, or left uncovered; and are capable of being woven by themselves, or in conjunction with other materials, into water-proof cloth. The difficulties in weaving arising from the ordinary elasticity of the material, are fortunately overcome by reducing the temperature of the threads, and by taking advantage of the property the threads have of eventually accommodating themselves to the stretched-out form. Their elasticity is again restored, after the weaving process is effected, by raising the temperature; this causes the cloth to be reduced in length without being increased in width.

Water-proof elastics thus formed, although very strong when pulled in the direction of the length of their fibres, are very weak when pulled transversely. To obviate this, Mr Goodyear has invented a species of fabric or 'artificial felt,' which, pulled in any direction, is very strong. This felt, covered with India-rubber in a pulpy state, which penetrates the interstices, is rendered still more cohesive, and forms a species of water-proof paper or 'real vegetable parchment,' useful in covering damp walls, &c. By covering a sort of woollen wadding with this, very light and warm water-proof cloth is obtained at a slight cost. Its applications are very numerous.

A species of velvet has been produced by means of caoutchouc, by J. Wansborough of London. It is effected by covering ordinary cotton or woollen cloths with a coating of glutinous caoutchouc, and strewing over this the different coloured wool-powders obtained by the shearing of cloths. This fabric is strong and water-proof, and is highly spoken of. It received a prize-medal in 1851.

By the important process of vulcanising India-rubber, it has its utility greatly increased, and is made to exhibit such properties, that it may be said 'to form a new substance.' The process is thus described:—The caoutchouc is immersed in a bath of fused sulphur, heated to a proper temperature, until, by absorbing a portion of the sulphur, it assumes a carbonised appearance, and eventually acquires the consistency of horn. The same condition can, however, be produced by either kneading the India-rubber with sulphur, and then exposing it to a temperature of 190° Fahrenheit, or by dissolving it in any of the common solvents, as turpentine, holding sulphur in solution or suspension. The *rationale* of this operation appears to be, that the India-rubber forms an actual chemical compound with the sulphur; becomes, in short, a sulphuret of caoutchouc, the properties of which are thus enumerated: The new compound *remains elastic at all temperatures;* vulcanised caoutchouc is not reducible by the ordinary solvents, neither is it affected by heat within a considerable range of temperature. Finally, it acquires extraordinary powers of resisting compression, with a great increase of strength and elasticity. This process was originally discovered by Mr Goodyear in America; but it was independently discovered in England by Mr F. Hancock: thus affording an instance of 'a novel solution of a problem which was known to be solvable, since it had been already solved.' A remarkable application of this material has been made by Mr Hodges, who uses it as door-springs, and as a projectile force.

By combining caoutchouc with sulphur and magnesia, Mr Goodyear has imparted to it the hardness and rigidity of wood, but at the same time a plasticity which enables it to be produced in a variety of forms. The manufacture of over-shoes of India-rubber is a branch of considerable importance, one company making no less than 3000 pair a day. Indeed, the manufacture of caoutchouc in its various forms is a remarkable instance of the rapidity with which special manufactures assume a high commercial importance. Thus, in America, Mr Goodyear has granted numerous licences to companies under his various patents, and has embarked in his manufactures the enormous capital of two millions sterling. It is right to notice, however, that the material enjoys a much more extended use in America than in Great Britain, for what are luxuries in the Old World, are often articles of everyday use in the New, even among the labouring classes.

Gutta-percha is of recent introduction into England, having been first brought under the notice of the Society of Arts by Dr Montgomerie in 1843. The tree from which it is procured is said to belong to the natural order *Sapotaceæ*, and is found abundantly in Singapore, the Malayan Peninsula, Borneo, and in all probability throughout the entire Indian Archipelago.

Gutta-percha comes to us in two forms: in thin slips or scraps, or in rolls, which are formed by rolling the thin layers together in a soft state. When pure, the slips are transparent, and somewhat elastic, varying in colour from a whitish yellow to a pink. In the mass, it is seldom free from impurities—such as saw-dust, pieces of leaves, &c. It is purified by a process called 'devilling,' or kneading, which is done in hot water: the water soon dissolves some of the foreign matters, and washes out others, until, after a short time, the gutta-percha is left in a mass, ductile, soft, and plastic, of a whitish-gray colour. Thus prepared, gutta-percha possesses very curious properties. Below the temperature of 50°, it is as hard as wood, but it will receive an indentation from the finger-nail. It is excessively tough, and only flexible in the condition of thin slips: in the mass, it has a good deal the appearance, and something of the feel, of horn; its texture is somewhat fibrous; and it offers great resistance to anything rubbed across it; a property which suggested what appears to have been its first application—as a substitute, namely, for horn for the handles of knives and choppers. By an increase of heat, it is made more flexible, until, at a temperature considerably below the boiling-point of water, it becomes like so much softened bees-wax. It is now easily cut and divided in any manner by a knife, and may be moulded into all varieties of form with the greatest ease; or it may be cut, and united again so perfectly, as scarcely to exhibit even the appearance of a joint, and possess all the strength of an undivided mass. Whatever be the shape into which the gutta-percha is formed while warm, it will retain precisely as it cools, hardening again to its previous state of rigidity. It is in a great measure devoid of elasticity, offering a striking contrast to caoutchouc, but its tenacity is little less than wonderful: a thin slip, an eighth of an inch thick, sustained a weight of forty-two pounds, and only broke with a strain of fifty-six pounds. It is impossible here to detail the vast variety of uses to which this substance is being put; indeed, time alone can determine the extent to which gutta-percha, and its congener caoutchouc, will be applied in the useful and ornamental arts.

Decorative Design as applied to Textile Manufactures.—In concluding our notice of the *materials* and the modes of *manufacturing* the principal varieties of textile

fabrics, it seems desirable to add a few remarks on those principles which are pretty generally received, regulating the application of ornament to the decoration of their surfaces. In placing these before the reader, we shall follow the order in which we have already discussed the varieties of textile fabrics, commencing with *linen*. Linen damask, as used for table-cloths and napkins, receives its ornament from a peculiar distribution of the threads in the weaving, surface-printing being rarely if ever applied to linen. In the application of ornament to this fabric, the designer should aim at flatness of treatment, avoiding all subjects in which relief is required. This excludes representations of architectural reliefed ornaments, fruit, and, indeed, all subjects perspectively treated. The design for a table-cloth naturally divides itself into two parts—the centre space and the border. In the border, or that portion which falls over the edge of the table, the lines should be flowing, while the centre space may be filled up with a diaper arrangement of geometrical figures, or conventionalised floral or natural forms well distributed.

Cotton.—The ornamentation of cotton fabrics is almost exclusively effected by surface-printing. The two great classes of ornamented cottons are *garment* and *furniture* fabrics. As colour is used very much in these fabrics, the designer must view the ornamentation he is desirous to carry out in a twofold aspect—form and colour.

True symmetry of form can only be obtained by a geometrical distribution. That 'ornament has a geometrical distribution, and is subject to symmetry and a correspondence of parts,' will be easily seen on considering that, in the words of Mr Redgrave, 'it is not possible to cover a large space with a repetition of small ornaments without *some* symmetrical arrangement developing itself.' And wherever the eye has a difficulty in tracing this symmetrical arrangement, it may be at once concluded that the treatment is unsatisfactory; it will, in fact, be wanting in the essential character of 'repose.' From these remarks, it will be inferred that 'dispersed' patterns, as they are called, applied to garment fabrics, are in bad taste—by dispersed being meant an irregular sprawling of the pattern over the surface of the fabric, in contradistinction to that symmetrical arrangement which we have above alluded to. The character of the ornamentation should also be attended to—leaves, sprigs, flowers, and simple scrolls being most suitable, and those of course treated flatly, avoiding all relief and perspective. Small forms will also be in better taste than large. The 'making up' and the 'nature' of the material have also to be observed. The first is very essential; and it is to a complete negation of the peculiarities of the human form that we see such monstrosities in garment fabrics perpetrated as *checks*, in which the pattern is made up by horizontal and vertical lines crossing each other. With reference to the nature of the material, the designer should remember that it has certain peculiarities which should not be lost sight of; that cotton, for instance, has not the surface lustre of silk, and that patterns applicable to the latter will, if applied to the former, display a want of truth. Again, cotton is a material easily cleaned; in fact, its most pleasing peculiarity is this idea of purity it conveys. Unlike wool, therefore, which partakes of opposite qualities, the pattern should be so arranged that a large portion of the surface be left in its natural condition. In deciding upon the form to be used, this point should not be lost sight of, that simplicity is elegance; all designs that are intricate in form, and multifarious in colour, contrast very unfavourably with those in which a simple ornament is judiciously distributed, and treated with a simple arrangement of colour.

The distribution of colour is an important point, and one on which much might be said; space only allows us to notice the received canon, that complete harmony, or perfect composition, is only attainable by a judicious admixture of the three primary colours, yellow, red, and blue.

The following is given by Mr Redgrave as an enumeration of the principles which should regulate the application of design to garment-fabrics. 'The ornament is always flat and without shadow; natural flowers are never used imitatively or perspectively, but are conventionalised by being displayed flat, and according to a symmetrical arrangement; and all other objects, even animals and birds, when used as ornament, are reduced to their simplest flat form. When colour is added, it is usually rendered by the simple local hue, often bordered with a darker shade of the colour, to give it a clearer expression; but the shades of the flower are rarely introduced.' It is worthy of note, that the fabrics in which those principles were applied in the Great Exhibition of 1851, were those exhibited by the East India Company. They shewed 'how much beauty may be obtained by simple means when regulated by just principles; and how perfectly unnecessary are the multiplied tints by which modern designers think to give value to their works, but which increase the difficulties of production out of all proportion to any effect resulting from them; nay, even to the absolute disadvantage of the fabric.'

In the treatment of *furniture fabrics*, many of the suggestions we have already given will be applicable. The prevailing aim has hitherto been to have large decided figures, giving ample scope for the display of gay and striking colours. Hence have originated vulgar gaudy patterns, in which obtrusiveness and want of *design*—using the term in its most significant sense—have been the chief characteristics. The symmetrical arrangement of a simple ornament with flat treatment, as already described, will be found much more pleasing than the absurd patterns too frequently used.

Silk and Woollen Fabrics.—The principles we have already indicated for the decoration of cotton, will be applicable in great measure to these; attention, however, must be paid to the nature of the material. Thus the beautiful peculiarity of silk, its brilliant lustre, must not be hid by any over-colouring or a redundancy of ornament; this, of course, does not refer to self-coloured silk, or to brocades where the ornament is of the same colour as the body of the material. Again, the nature of wool admits of a greater redundancy of ornament, and a larger amount of colour.

The following we give, in conclusion, as the principles applicable to printed garments, sanctioned by the Department of Practical Art. 'The ornament should cover the surface, either by a diaper based on some regular geometrical figure, or growing out of itself by graceful flowing curves.

'The *size of the pattern* should be regulated by the material for which the design is intended—small for close thick fabrics, such as ginghams, &c.; larger for fabrics of more open texture, such as muslins, Bareges, &c.; largely covering the ground on de laines, and more dispersed on cotton or linen goods.'

Carpet Decoration.—The main idea which a carpet should convey is an easy natural surface to walk upon, and not obtrusive—that is, it should look flat, and its colours should be 'subordinate to the more prominent pieces of furniture.' Hence all carpets in which huge flowers or floral subjects, architectural ornaments, and the forms of living objects, are portrayed in high relief and with perspective effect, and which 'challenge attention by the brilliancy of their hues in masses, or the tortuosity of the lines in the boundaries of their forms,' are considered to be in bad taste; and hence, also, the principles which dictate flat forms, without shadow or relief, and well distributed over the whole surface. As regards colour, all violent contrasts should be avoided, and 'graduated shades of the same colour, or a distribution of colours nearly equal in scale of light and dark, should be adopted; secondaries and tertiaries, or neutralised primaries, being used rather than pure tints, and lights introduced merely to give expression to the form.'

MINING—MINERALS.

THE term *Mineral* is somewhat varied and indefinite in its application. In the widest sense, it is made to embrace the whole of inorganic nature; and thus we speak of the mineral in contradistinction to the vegetable and animal kingdoms. Occasionally, it is restricted to those native products which appear in a crystallised or definite form; but more generally and properly it is extended to all the earths, rocks, salts, and ores which are obtained from the crust of the earth. Employing it in the latter signification, we intend, in the present sheet, to treat of the nature, origin, and uses of such substances as coal, limestone, sandstone, rock-salt, sulphur, gems—reserving consideration of the metallic ores and metals for a subsequent number. It is almost superfluous to observe, that the mining, digging, transport, and preparation of these materials for application to the purposes of civilised life, constitute departments of human industry of high scientific, as well as economic importance.

For the more accurate comprehension of the subject, it may be necessary to premise that we speak of the *crust* of the earth—meaning thereby that superficial rind or portion accessible to human investigation—in contradistinction to the interior masses, concerning the nature of which we can only form conjectures. In this crust the rocky substances are variously arranged: some are found in layers or strata—hence said to be *stratified;* others appear in vast irregular masses, presenting no trace of bed or layer, and are accordingly termed *unstratified*. The matter of the stratified has evidently been deposited from water, and from this view of their origin, they are generally known as *aqueous* or *sedimentary* rocks; while the unstratified, presenting no appearance of deposit, but everywhere an irregular configuration, and, moreover, often breaking through and contorting the stratified, are considered of *igneous* or *volcanic* origin. Both sedimentary and igneous rocks present various mineralogical and chemical characters: thus, of the former, we have roofing-slate, sandstone, coal, limestone, &c.; of the latter, granite, basalt, and lava—all very distinct in composition and appearance. Besides differences in mineral composition, the sedimentary rocks contain different kinds of fossils—that is, the petrified remains of animals and plants; and such distinctions have rendered it necessary to arrange the rocks constituting the crust of our globe into various *formations*—meaning by a formation any suite of rocks possessing some peculiar mineral or fossil character. Thus we speak of the 'coal-formation,' meaning thereby not merely the beds or layers of coal, but the sandstones, shales, ironstones, and the like, which alternate with and accompany that mineral—seeing that the whole have been evidently deposited under similar conditions, and that similar organisms are found fossil within them. Further, both the stratified and unstratified rocks are frequently traversed by rents and fissures, some of which are entirely void, others partially filled or lined with crystallised products differing from the adjacent rocks, and many, again, wholly filled up with crystallised substances, metallic ores, and other ingredients, constituting what are termed *lodes* and *veins*. (See GEOLOGY.)

BITUMINOUS SUBSTANCES.

Bitumen—from a Greek word signifying the pitch-tree—may be regarded as embracing all those inflammable minerals which, like pitch, burn with flame and smoke in the open air. Naphtha, petroleum, and asphalt are familiar examples; but all substances impregnated with these bitumens are said to be *bituminous*. Hence under this head may be included coal in all its varieties, as well as bituminous slate, slaggy mineral pitch, and the asphalts of commerce.

Coal.

Coal, of which there are several distinct varieties, is one of the most important minerals with which man has yet become acquainted. It is uncertain when coal first began to be used in Britain as fuel, but in all probability it was not earlier than the beginning of the twelfth century. In 1281, Newcastle is noticed as having some trade in that article; and a little later we find it mentioned in the chartulary of the Abbey of Dunfermline. In the reign of Edward I., its use in London was prohibited, in consequence of the supposed injurious influences of the smoke; and this prohibition we find renewed at several subsequent periods, but all to no purpose. The increasing scarcity of wood as fuel rendered some other substitute necessary; and, from its compact form and powerful heat, no known substance could for one moment be brought into competition with coal. The smoke-nuisance was therefore submitted to; and, despite of every obstacle, the 'obnoxious' mineral was soon in the ascendant. At the beginning of the sixteenth century, it seems to have been getting into use in the Lowlands of Scotland, where we find Boethius taking notice of a 'black stone' found in Fife and the Lothians, the heat of which was sufficiently intense to fuse the most refractory metals. Since the time of Charles I. it has become almost the only description of fuel used in London, and in most other towns and districts throughout the kingdom—peat or turf being but occasionally employed, and that solely in remote localities. It is within the current century, however, that the great demand has been made upon our coal-fields; since the application of the steam-engine to the purposes of the mine, the factory, the railway, and river; since the introduction of gas, the extension of our foundries, and the general advancement of those economical processes which distinguish the present from every other period of our country's history. According to the most recent estimates, not less than forty millions of tons of coal are raised from the different mines in the British Islands, of which between three and four millions are exported to other countries.

The coal worked in Britain may be said to be exclusively obtained from the great coal-formation, where it alternates with strata of sandstone, bituminous shale, bands of ironstone, fire-clay, and impure limestone—the whole suite being usually termed the *coal-measures*. Attempts have been made to work the thin beds found in more recent formations, as the oolite and tertiary, but in every case without much success. The principal districts, or 'fields,' as they are called, are those of Northumberland and Durham, Lancashire, Stafford, South Wales, and the Lowlands of Scotland—the latter extending from Fife to Ayrshire at an average breadth of about thirty miles. In these fields there may be as many as ten, twenty, or even forty seams or strata of coal, varying from a foot to thirty feet in thickness; but of these, in general, not more than five or six can be worked with profit. The mineral so obtained is of different varieties and qualities: so pure, as to leave after combustion the smallest percentage of ash; or so foul, as to be burned with difficulty. The principal varieties are—*caking* coal, a highly bituminous sort, like that of Newcastle, which emits much smoke and gas, and cakes together during combustion; *cubic*, which is also bituminous, but breaks

into larger cubical masses, and does not cake while burning; *splint*, a hard slaty variety, which is still less bituminous, and does not cake, but burns with great heat, and leaves little ash; *cannel*, a compact variety, also bituminous, burns with a clear flame, does not cake, and leaves a whitish ash, principally used, where it can be obtained, for the manufacture of gas. All these varieties are less or more bituminous; but there is another variety, known by the name of *anthracite*, or 'blind coal,' which is non-bituminous. This anthracite has a glistening and semi-metallic aspect, does not soil the fingers when rubbed, and burns without smoke. It is, in fact, a natural coke, or charcoal, the original coal having been deprived of its bituminous products by heat or other causes. It is found in small patches in several coal-fields in contact with the igneous rocks, which have evidently produced the change, but abundantly in South Wales, where it occupies a considerable area. It is used exclusively in the reduction of the metallic ores, for which it has been employed only since the introduction of the hot-blast process. Several fields, both of bituminous and anthracite coal, occur in Ireland; but comparatively little is raised, and almost all the coal used in Dublin, Belfast, and other large towns is imported from England.

Besides the supply obtained in Britain, there are coal-fields, less or more extensive, in France, Spain, Belgium, and Germany; in India, China, the East India Islands, Australia, and New Zealand; in Nova Scotia, and the states of North America; in the Isthmus of Panama, Chile, and Peru; and even in some of the islands of the Pacific and Arctic Oceans. Of these fields, the North American are by far the most extensive and important, presenting areas of bituminous and anthracite coal greater than the whole extent of our own island. That of Pennsylvania, Virginia, and Ohio, for example, extends continuously from north-east to south-west for a distance of 720 miles, its greatest breadth being 180 miles; its area thus amounting to 129,600 square miles. That situated in Illinois, Indiana, and Kentucky, embraces an area of 14,000 square miles; while several, many times larger than the largest coal-field in Britain, are found in Michigan and other parts of the Union. Many of the coal-fields in the world are yet untouched; it being only after the wood of a new country has been used up, and civilisation made some progress, that man betakes himself to the difficult and often dangerous task of extracting mineral fuel. All the coal-fields now mentioned belong to the same great formation; but there are other patches of a more recent date which are occasionally worked, as the lignite, or brown coal of Germany, and of Bovey Hayfield, near Exeter. This, however, is a very different material in comparison, and is only had recourse to where the lower formation is absent, or at such a depth as to preclude its easy working. Taking, therefore, an estimate of the whole amount of coal known to exist, there need be no dread of the supply being exhausted for thousands of years to come; for though the fields of one country should be exhausted, the fields of another lie patent to the same commercial influence which imports tea from China, cutlery and cloth from Britain, and cotton from America.

Coal being, in every instance, a true stratified rock, the modes of obtaining it are much the same in the different countries where it is sought after. In early times, our ancestors could avail themselves of little more than the mere outcrop—that is, that portion of a seam which approaches the surface—and this was excavated just as a stratum of limestone or sandstone is quarried at the present day. By and by, they sank to greater depths, but still entering in a slanting direction, after the dip or inclination of the strata, and not descending by shafts or perpendicular pits, as is now the practice. To rid their workings of water, they hewed long tunnels or subterranean drains from some low level, and carrying this forward to the seam of coal, effected a drainage to that depth. Where the coal-seams lay on high ground, and where there was any deep glen or ravine in the neighbourhood, such drainage often allowed them to work at a considerable depth; but these *day-levels*—so called from their discharging their contents to the open day, in contradistinction to other levels within the mine—were, upon the whole, but imperfect and expensive affairs. In some instances, where pits were sunk, windmills were erected for the purpose of pumping the water; but no certain effect could be calculated upon from an agency so unstable as the wind. The invention of the steam-engine soon set aside these rude and imperfect appliances; shafts, instead of slanting adits, are now everywhere sunk, and the water brought to the surface at once, no matter whether the depth be 30 or 300 fathoms. Of course the fittings of a coal-mine depend, as do all other commercial speculations, upon the value of the material sought to be obtained. In some districts, the shafts are of no great depth, the pumping-engines small and rude, and the mineral brought to the surface simply by animal power; while in other localities the shafts are of enormous depth and finely executed, the engines of great magnitude and superior finish, and no animal power employed unless in the hewing of the coal. In Britain, a Newcastle colliery may be taken as the most perfect of its kind. Here the shafts, which are often sunk at vast expense, vary from 150 to 300 fathoms in depth, are lined with casings of stone, wood, or iron, and are divided into various compartments for the accommodation of the pumping-gear, and the ascending and descending corves which contain the coal—these compartments also subserving an important end in the ventilation of the mine. Having reached the stratum of coal, which generally lies at a considerable inclination, main *drifts* or excavations are made in different directions for drainage, transit, and ventilation; and then the minor workings branch off from these, care being taken to leave pillars or masses of the stratum for the support of the superincumbent material. The water that oozes from the workings finds its way to the lower level, or *sump*, of the pit's bottom, from whence it is pumped up by a powerful engine; and the coal hewn out is brought from the various workings to the main drifts, whence it is dragged by ponies to the bottom of the shaft, and raised in corves, or baskets, to the surface.

Were the accumulation of water the only obstruction to the mining of coal, the difficulty could be easily surmounted. A supply of fresh air, however, must be regularly and unceasingly maintained in every part of the workings; and not only so, but care must be taken to prevent the accumulation of two gases most destructive to human life—namely, carburetted hydrogen and carbonic gas—the *fire-damp* and *choke-damp* of the miners. For this purpose, the various underground workings are so arranged and boarded off, that while one set receives the descending current, another carries it forward again to the pit bottom, where, by means of rarefaction, produced by a huge fire, it is carried up the shaft to the atmosphere. By these means, not only is fresh air supplied to the miners, but the deleterious gases are carried off, and the whole subterranean recesses rendered safe and healthy. The most ingenious of human inventions are, however, imperfect; and fire-damp will exude from the coal-seam, and lurk in recesses, there either to suffocate the first comer, or to explode the instant that a lamp is brought in contact. To prevent these casualties as much as possible, various air-tight trap-doors and boardings are employed, and the miner is furnished with safety-lamps of various constructions, which, while they afford sufficient light, prevent the carburetted hydrogen from coming in contact

with the flame within (see fig. on preceding page).* These remarks apply in particular to the Newcastle coal-field, where, in consequence of such difficulties, coal-mining is conducted with greater care and skill than in any other district; but it must be remembered that there are many fields where fire-damp is unknown, and where the most ordinary ventilation is sufficient to prevent the accumulation of any obnoxious gases. In some of the largest Pennsylvanian mines, the anthracite is of great thickness, and so exposed and level, that it is hewn out either in open quarry or in huge drifts, precisely after the fashion of our railway tunnels.

The value of the coal actually brought to the surface in Britain amounts annually to upwards of ten millions of pounds sterling, and almost the whole of this is derived, although in unequal proportions, from the Newcastle, the South Welsh, the Staffordshire, and Scotch coal-fields. With regard to the first of these—the Newcastle coal-field—it is said that upwards of six millions of tons are there annually raised up out of the bowels of the earth; that 60,000 persons are employed in the mining operations; that 1400 vessels are constantly engaged in conveying the coal—amounting to three millions of tons—required for the consumption of the metropolis alone.

As to the origin of coal, no matter what the variety, there can be no doubt that it is essentially vegetable. Not only are fossil trunks, branches, leaves, and fruits found in the mass, but when submitted to the microscope, it often shews the ducts and fibres of a true vegetable structure. We know, moreover, that vegetable matter, when subjected to moisture and pressure, and excluded from the action of the air, will in a short period pass into a bituminous or carbonaceous mass, which time and greater pressure and heat would by and by convert into true mineral coal. Peat, were it excluded from atmospheric influence, would soon pass into a species of coal: brown coal and lignite, in which the trunks and branches of the trees are still perceptible, are only varieties less perfect than the true coal; and even in the old coal-formation itself, various beds present various degrees of perfection, according as the vegetable mass seems to have been more quickly and perfectly removed from the action of the atmosphere. How the masses of vegetable matter were accumulated, is still a subject of speculation with geologists—some contending that the trees, grasses, ferns, &c., which compose it, must have grown and accumulated just as peat-mosses do at the present day, and that the land was then submerged, and the mass covered over by layers of sand and mud, which, hardening, formed strata of stone and shale; others reject this theory as untenable, and consider the whole strata—sandstone, shale, &c.—of the coal-measures to have been deposited in estuaries liable to periodic inundations, like those of the Niger and Ganges, but only on a more gigantic scale. According to this notion, which is more in accordance with the phenomena presented, coal is partly composed of vegetables which grew *in situ* in the form of jungle, and partly of masses drifted down from the interior by the waters of the river.

In the autumn of 1853, a lengthened jury-trial took place in Edinburgh, in reference to a peculiar mineral found in large quantity near Bathgate, in Linlithgowshire, and the point at issue was, whether the said mineral *was coal*, or *was not coal*. Two names were given to the substance—namely, 'the Boghead Coal,' and 'the Torbanehill mineral;' and the greater number of the professional chemists, botanists, microscopists, geologists, and mining engineers of Great Britain, as also managers of coal-pits, and even working colliers, gave evidence on the one side or the other. The substance under dispute is a hard slaty-looking mineral, with a more or less earthy-brown colour. When an iron instrument is drawn across it, a light-coloured streak is produced, which is not at all lustrous. Certain parts reduced to powder have a yellow tint resembling mustard; other parts yield a much darker powder. Its fracture is at times conchoidal, and at other times slaty. When heated in a close vessel, as in a gas-retort, the Boghead Coal gives off a very large amount of gas of excellent quality, and leaves behind a coke or residue to the extent of about 30 per cent. This coke contains only two or three parts of carbon, and the remainder—27 or 28 per cent. of the original mineral—is composed of white ash or earthy matter. Now, the parties who advocated that the material in question was *not coal*, contended that all true coals had a lustrous streak, and left, when heated in a retort, at least 50 per cent. of coke, of which not more than 10 per cent. was ash; at the same time, they recognised a class of *bituminous shales*, into which they threw the Boghead mineral and all other combustible minerals having more than 10 per cent. of ash. On the other hand, it was asserted that a lustrous or non-lustrous streak was not characteristic of coal; that a difference of 10, 20, or more per cent. in the proportion of the ash was no sign whereby to determine definitely what was coal; and that, however convenient it might be to recognise in commerce a class of combustibles styled bituminous shales, yet all such shales were in reality mere varieties of coal. In short, they considered that under the term coal, those substances must be comprised which consist of compressed and chemically altered vegetable matter, associated with more or less of earthy substances, and capable of being used as fuel. The jury, upon deliberation, agreed with the latter view, and returned a verdict that the Boghead mineral was a coal.

Jet—Amber.

Though the chief use of coal be doubtless that of producing heat and light, there are certain minor purposes to which some of the varieties are applied. Thus we have occasionally seen very pretty vases, and other ornaments, made from cannel-coal when it is sufficiently compact and lustrous. It is easily turned on the lathe, and takes a polish which is not readily tarnished; the only objection to its use being brittleness, and liability to be injured by fire.

Jet, of which necklaces, ear-rings, and other ornaments are made, is but a variety of coal, as common in its origin and nature as that which we pile on our fires. It is occasionally found in the lignite beds of England, but principally in Germany and Prussia, where it occurs associated with amber, which is regarded as a fossil gum, while jet seems to be the trunk and branches of trees more completely bituminised, and freer from earthy impurities than cannel or other coals. It is easily turned on the lathe, or cut with the chisel, and is susceptible of a fine polish. Imitations of jet are extensively manufactured by the glass-maker; but these may be readily detected by their greater hardness and weight.

Amber, a well-known yellow resin-like substance, is a fossil gum or resin. It is solid, brittle, commonly

* The safety-lamp, invented by Sir Humphry Davy, and introduced to the miners in 1816, consists of an oil-lamp enclosed in a wire-gauze cylinder, of which the apertures are extremely minute—a square inch of the surface containing 625 openings. Through apertures so small, flame will not pass, and the lamp may therefore be carried into the most explosive atmospheres without risk. When the fire-damp is to the air in the proportion of 1 to 5, 6, or 7, the cylinder is filled with the flame; but even though the wire-gauze should become red-hot, the exterior air is not kindled. If the miners would always employ this safeguard instead of candles, there can be little doubt that fewer explosions would occur; but the feeble light which it affords renders it unacceptable, and men will actually risk their lives for the sake of a little more light and the avoidance of a little trouble. In many pits, a *locked* Davy is delivered to the pitmen, who return it to the overseers before leaving the pit.

transparent, and, when rubbed, becomes electrical. It is found in various countries, more particularly on the Adriatic and Sicilian shores; on the Baltic, between Memel and Danzig, where there are regular mines of it; and in Japan, Madagascar, and the Philippine Islands. It is used chiefly in the manufacture of beads, necklaces, trinkets, and various ornaments, for which purpose it is easily cut, and takes a beautiful polish. Dissolved by drying linseed oil, it forms amber-varnish. The largest known specimen of amber was found near the surface of the ground in Lithuania, about twelve miles from the Baltic. It weighs eighteen pounds, and is in the royal cabinet at Berlin. Other curious specimens have been detected enclosing insects, and even drops of liquid.

Naphtha—Petroleum—Asphalt.

Naphtha, petroleum, mineral pitch, and asphalt, may in a great measure be regarded as members of the same class, as they are composed of the same elementary substances, carbon and hydrogen. Naphtha, on exposure to the air, soon loses its limpid appearance, and passes into a kind of petroleum; and petroleum, under similar treatment, dries and shrinks into a viscous slaggy state, undistinguishable from native mineral pitch.

Natural naphtha is a limpid, or but slightly coloured bitumen, highly inflammable, and of a strong bituminous, but not disagreeable odour. It is found at Baku on the Caspian, at Hit on the Euphrates, and at other places in Mesopotamia: it occurs abundantly in the lower districts of the Burman Empire; exists at various places in the north of Italy, as Piacenza, Modena, &c.; and in some districts of North America. It generally exudes from fissures in the rocky strata, or is collected in shallow wells, dug in the clays and shales where it occurs. A similar liquid can be obtained by distilling petroleum, coal-tar, and other bitumens; but the artificial product has a more penetrating and unpleasant odour. Naphtha has the property of dissolving most of the essential oils and resins, and is at present largely used as a solvent of caoutchouc. It is also used for lamps; and the cities of Parma and Genoa are said to be lighted with the produce of the wells in the duchies of Modena and Parma. A very fine black pigment may be prepared from the soot of naphtha lamps.

Petroleum, or rock-oil, is another liquid bitumen, of a brownish colour and variable consistency, and yielding a strong disagreeable odour. It is found exuding from various secondary strata, but chiefly in coal districts, where it is evidently a product of that formation. It occurs in small quantities in various localities of Britain, but abundantly in other countries of Europe, in Persia, the Burman Empire, in Texas, and in the islands of Trinidad and Barbadoes. On exposure to the air, petroleum thickens, and assumes a darker hue, in which state it is generally known by the name of mineral pitch, or Barbadoes tar. On further exposure, and especially when mingled with earthy impurities, it passes into a solid state, then becoming the common asphalt or bitumen of commerce. In its ordinary liquid state, it is burned for light; worked into balls with earth and gravel, it is used in Eastern countries as fuel; and mingled with grease, it is occasionally employed as a substitute for tar in coating vessels.

Asphalt, so called from its adhesive nature, differs from mineral pitch in being solid and brittle at the ordinary state of the atmosphere. It melts easily, and is highly inflammable, leaving, when pure, little or no ash after combustion. It is found in most of the localities where petroleum springs occur, being nothing more than their accumulated produce. The chief supplies are obtained from the shores of the Dead Sea, from Barbadoes, from Trinidad, where it occupies a basin or lake about three miles in circumference, and from Clermont, Seyssel, and Bourg in France, where it occurs in limestone and calcareous shales. Asphalt was employed by the ancients in some of their cements, and also in the process of embalming. It is now extensively used in the formation of pavement, roofing, and other economical purposes. Melted and mingled with properly sifted gravel, or iron slag, it forms a very durable and unexpensive pavement, being liable to be softened, however, during intense heats.

CALCAREOUS SUBSTANCES.

Under this head we include such economic minerals as contain a notable proportion of *calx* or lime in their composition. Common limestone, magnesian and lithographic limestones, marble, chalk, marl, gypsum, and alabaster, are familiar examples. Some of these have evidently been deposited from calcareous waters; others are as evidently the production of animalcules, like the coral polype; and some are almost wholly composed of the shells of mollusks and of other calcareous exuviæ. Whatever may have been their several origins, they have all undergone certain structural changes since their formation—thus rendering them less or more compact and crystalline, producing a dull massive rock or a brilliant marble, an opaque gypsum or a translucent alabaster. Chemically, they have one common basis—namely, *calcium*, a substance obtained with difficulty in the laboratory, and never found as a natural product. It is one of the metallic elements discovered by Davy, and so extremely oxidable, that on exposure to the air it is almost instantaneously converted into lime (oxide of calcium); and this lime, if further exposed, becomes a limestone or carbonate of lime, by absorption of moisture and carbonic acid.

Common Limestone.

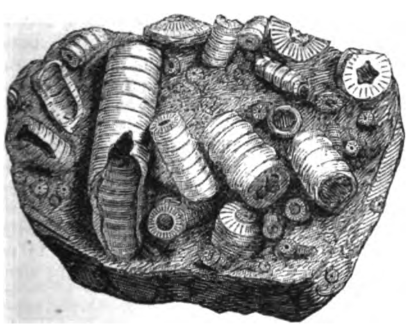
Limestones fit for building and agricultural purposes are found in every formation, from the oldest to those of the most recent origin—being crystalline and concretionary in the primitive and transition series, but gradually losing this structure, and becoming more earthy in the secondary and tertiary strata. In all of them there is a certain amount of impurities, consisting for the most part of clay and sand, with traces of iron and other ingredients. The economic value of any limestone, as well as its fitness for any particular purpose, must depend therefore upon its actual composition, and not upon its absolute purity as a carbonate. The rock is generally dug from open quarries, but occasionally, when it dips slowly, and is worth the expense, it is followed downward by mining, the greater part of the stratum being excavated, and only portions left at intervals to support the superincumbent material. It is then broken into fragments of moderate size, and conveyed to a kiln, where, being placed in alternate layers with coal or turf, it is roasted, thereby expelling its water and carbonic acid. In the best contrived kilns, the process is carried on continuously; broken limestone and fuel being constantly thrown in at the top, and the burned lime raked out at intervals from beneath. In this state it is known as *shell*, *unslaked* or *caustic lime*, and requires to be moistened with water to convert it into powdery quicklime or *slaked lime*. Occasionally, when the limestones contain a considerable percentage of silica (sand), and the heat been very high, the lime refuses to slake, and is said to be *over-burned;* in other words, a portion of silicate has been formed. Quicklime is a soft bulky powder soluble in water; and what is remarkable, the colder the water, the larger quantity of lime is taken up. Thus a pint of water at 60° will dissolve eleven grains; while at 212°, or the boiling-point, only seven grains are retained in solution. As stated under FICTILE MANUFACTURES and APPLIED CHEMISTRY, quicklime is largely employed in the formation of mortar and cements, in glass-making, leather-dressing, dyeing, and bleaching; and, as will hereafter be seen, its uses are not less important in agriculture, in the purification of gas, in medicine, and other industrial processes. Applied to land, it promotes

the decay of vegetable matter, neutralises the effects of certain hurtful compounds of iron, and serves to liberate potash from the insoluble silicates of that base contained in the soil. Lime-water for chemical and pharmaceutical purposes, is always prepared by agitating cold water with excess of quicklime in a closely stoppered vessel, and then, after subsidence, pouring off the clear liquid. Besides the above applications, a large quantity of limestone is used as a flux in metallurgy, such strata being sought for this purpose as contain but a small percentage of impurities.

Limestone is one of the most abundant of rocks, there being no district of any extent in which it does not appear as a member of one or other of the geological formations. In Great Britain and Ireland, the supply is inexhaustible: it is worked in beds from a few feet to one hundred in thickness; the mountain or carboniferous limestone, which underlies the coal-seams, often exceeding that thickness, and ranging unbroken for many miles in extent.

Marble.

Marble is but a technical term for any species of limestone sufficiently pure and compact to be susceptible of a fine polished surface. No matter what the colour, whether white or black, whether studded with the strange forms of fossils or streaked with the most fantastic veinings, marble is but a carbonate of lime, containing only a few subordinate impurities, which do no more than affect its colours and markings. The best varieties are obtained from the primary and transition formations, in which they occur granular, crystalline, and not unfrequently replete with party-coloured veinings. Pretty enough marbles for slabs and other architectural purposes are sometimes obtained from the secondary formations, these being, in general, curiously marked with the shells, encrinites, and other



Fragment of Encrinital Marble.

corals which are imbedded in the mass. None of these, however, are susceptible of the same degree of polish as the primary marbles, some of which, like that of Carrara, seem almost translucent. Most countries of any extent have varieties of native marbles, which, though inferior to those of Italy and the Archipelago, might still be more extensively used than they are, were it not for the expense in cutting and polishing, and, above all, for the rapidity with which many of them become weathered and tarnished.

Sculptors and architects generally arrange the marbles of a country into some such divisions as the following: —*Uni-coloured*, as the black and white; *variegated*, when marked with irregular spots and veins; *madreporic*, when studded with encrinal or coral markings; *shell*, when only a few shells are interspersed through the mass; *lumachelli*, entirely composed of shells; *cipolin*, containing veins of greenish talc; *breccia*, marbles formed of angular fragments of different composition and colour; and *puddingstone*, when the fragments are round instead of angular. The celebrated marbles of Greece and Rome, such as the Parian, the Pentelic, the Carrara, &c., were of one uniform colour, and only occasionally marked with grayish or greenish veins. Besides these, which were chiefly employed in sculpture, and in the decoration of their public edifices, the ancients indulged in a variety of fancy marbles for minor ornamental purposes—such as black, red, green, yellow, spotted, and veined. The localities of some of these ancient marbles are lost, but inexhaustible supplies of first-rate statuary and architectural marbles can still be obtained from the Archipelago, from Carrara, Genoa, Corsica, Sicily, and other parts of Italy. At Carrara alone, about 1200 men are employed at the different quarries, and at the mills for sawing the marble. The annual rental is calculated at about £28,000, and the value of the yearly exportations of the raw material is not less than half a million. So accessible are these quarries, and so free from flaws is the rock in some portions, that blocks of more than 200 cubic feet can be detached by means rude and primitive compared with quarrying in Britain. The value of the material differs according to the quality and size of the block; large blocks ranging from £2 to £3 per cubic foot.

Many marbles of excellent quality are found in France; in England, they are abundant in the counties of Derby, Devon, and Anglesey, the last being of a green colour; in Scotland, at Assynt, Ballahulish, and in the islands of Tiree, Skye, and Jura; and in Ireland, at Kilkenny and other places. The Kilkenny marble is black, and encloses shells of a whitish colour, which, when cut across and polished, present various circular markings, which add to the beauty of the slab. The United States also furnish some excellent architectural marbles, principally of primary formation. One range, which passes unbroken through several of the states, is perhaps one of the most extensive and valuable primary limestones in the world. It is of a pure white colour, and of a highly crystalline texture, affording blocks of more than fifty feet long and eight feet thick. It is employed in several of the states' public buildings —as, for example, the City Hall of New York, and Girard College, Philadelphia.

The applications of marble are so numerous and common, that we need here merely indicate its use in building, statuary, and monumental erections; in internal decoration, as mosaic-work, mantel-pieces, vases, table-slabs, and other articles of furniture. Party-coloured stones susceptible of a high polish, as porphyries, serpentines, and the like, are commonly but erroneously termed and classed with 'marble'—a term which is applicable alone to rocks essentially composed of carbonate of lime, and susceptible of polish as above described. As limestones, all marbles are consequently corroded and acted upon by acids; while porphyries and serpentines being essentially silicious, are not so affected. Even alabaster, though having a calcareous base, is not in the above sense a marble; but is, as will shortly be seen, a sulphate of lime incorrodible by acids. The preparation of marble as an ornamental material is simple but laborious. The blocks are generally detached from the quarry by sets of iron wedges —blasting by gunpowder being apt to produce rents and flaws where least wanted. They are next reduced by hammer and pick, and finally chiseled into the desired form. Slabs are obtained by cutting the blocks asunder with a thin plate of soft iron, under which sand or grit, liberally supplied with water, acts as the cutting agent. Pieces of moderate size are generally cut by hand; but where the blocks are large, machines of various constructions are employed. Marble-cutting, indeed, is the subject of several patents, in which machinery, moved by steam or water, effects not only plain cutting and polishing, but even mouldings and ornaments of an intricate kind. In polishing, sharp sand, emery, tripoli, and tin-putty are the substances

employed—the workman graduating his material with the increasing smoothness of the surface. The body with which the sand is rubbed upon the marble is usually a plate of iron; but for the subsequent process, a plate of lead is used, with fine sand and emery. The polishing rubbers are coarse linen cloths, wedged tight into an iron planing-tool. Throughout the whole operation, a constant supply of water is indispensable.

Magnesian Limestone—Magnesia.

Magnesian limestone, which appears extensively in England, Germany, and other continental countries, occurs often in beds of great thickness, immediately above the coal-measures, just as the mountain or carboniferous limestone lies immediately beneath. It is usually of a cream-yellow colour, and of very variable consistency, some layers being soft and powdery, others irregularly crystalline and concretionary, and some compact and homogeneous. The compact granular variety is generally known by the name of *dolomite*, after Dolomieu, a French geologist. Magnesian limestone is, for the most part, used as the ordinary carbonates of lime—that is, for agricultural and building purposes—some of the English quarries furnishing an exceedingly durable material. The new Houses of Parliament, for example, are built of a magnesian limestone, that of Bolsover Moor, in Derbyshire, having been selected after the most rigid scientific tests of a commission of inquiry. Besides these uses, some of the more compact and homogeneous schists are employed for lithographic blocks, the chief supply for that purpose being derived from Germany, though lithographic schists are also obtained from the white lias limestone in England. (See LITHOGRAPHY.)

Magnesian limestone is so called from its containing a notable percentage of magnesia—a well-known medicinal earth, commonly obtained by burning the carbonate of magnesia. Magnesium is the metallic basis of magnesia, just as calcium is the base of lime; it is strictly a product of the laboratory, and does not occur in nature. The *calcined magnesia* of the druggist is procured either from this source, or from the bittern of sea-salt, or from the waters of certain springs impregnated with the sulphate of magnesia. The hydrated carbonate of magnesia, the *magnesia alba* of the shops, is also obtained by a chemical process from the sulphate. Natural carbonate of magnesia exists as a component part of many mineral substances, making them feel soft and soapy to the touch. *Sulphate of magnesia* (Epsom salts) is obtained, by a simple process, from bittern, by treating magnesian limestone with dilute sulphuric acid, or from certain mineral springs—as, for example, those of Epsom in Surrey, which give to the salt its most familiar name. This salt is one of the most common and useful in medicine, and is, moreover, the chief source of the other forms in which magnesia is administered.

Meerschaum (German, *foam of the sea*), a substance in great repute among tobacco-pipe fanciers, is an earthy carbonate of magnesia, extremely light, and of a yellowish-brown colour. It is found in various parts of Southern Europe, particularly in Greece and Turkey, where, besides being fashioned into pipe-bowls, it serves also the purposes of a fulling-earth. Germany, however, is the great seat of the meerschaum-pipe manufacture, whence France and England obtain their supplies. The substance is first soaked in tallow, then in wax, fashioned into the desired form, and finally polished with shave-grass.

Chalk.

Chalk, another well-known mineral, is a carbonate of lime of a white or whitish-gray colour, having a soft meagre feel and earthy fracture. It is the last or youngest of the secondary rocks, and constitutes an important geological feature of England—the chalk-hills which form the white cliffs of our southern shores having conferred the ancient name of *Albion* (*alba*, white) upon our island. Calcined like common lime, it is used for manure and cement, in polishing metals and glass, in painting and whitewashing, and in various other processes. For the last purpose it is purified by trituration and elutriation, and sold under the name of *whiting*, or *Spanish white*. The chalk-formation yields also the flint of commerce; but this more properly falls to be considered under the class *silicious substances*. What are called *Drawing-chalks* have no relation to this substance. *Red* chalk, for example, is a clay, coloured with peroxide of iron, found in several localities; and the *French* chalk used by artists is a soft magnesian mineral, allied to steatite. *Crayons* are usually made of fine pipe-clay coloured with metallic pigments.

Marl—Calc Sand.

Marl is one of the most recent calcareous deposits, being in many places still in the course of formation. Though essentially a mixture of carbonate of lime and clay, it occurs in various states of purity, from a marly clay, which will scarcely effervesce under acids, to shell-marl, containing from 80 to 90 per cent. of lime. *Marl-clay*, for instance, occurs as a whitish friable clay, with an admixture of lime, and sometimes also of magnesian earth; the term *clay-marl* is used when the calcareous matter prevails over the clay. *Shell-marl* is almost wholly composed of lime and fresh-water shells, with a trace of clay and other earthy matter, and where solidified by chemical aggregation, is known as *rock-marl*. Marl uniformly occurs in valleys formerly the sites of lakes, or in existing lakes, and seems to be partly derived from the waters of calcareous springs which enter such lakes, and partly from the shells and secretions of the fresh-water mollusks which inhabit them. It is dug from open excavations, and applied to certain soils as a manure, or as a top-dressing for pasture.

Calcareous sand, which consists almost entirely of comminuted shells, is another recent product occasionally employed as a fertiliser. It is found in layers in ancient or raised beaches, and in masses by the sea-shore, where, thrown up by the waves, it often consolidates into beds of considerable thickness. As an instance of its value, Sir H. de la Beche mentions that between five and six millions of cubic feet are annually conveyed from the Cornish coasts, to be spread over the land in the interior as a mineral manure. As shells consist almost wholly of carbonate of lime, with a little animal matter, it would be more advantageous in most cases to reduce them to quicklime, which must be much more energetic in its action as a fertiliser.

Gypsum—Alabaster.

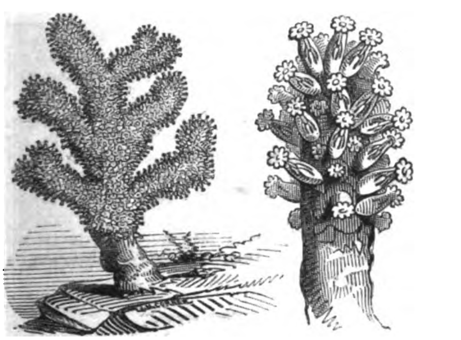
Gypsum, also known as sulphate of lime and plaster of Paris, is found in England, and in many other countries. It occurs in various states of crystallisation and purity: thus the ordinary gypsum of commerce is soft, and imperfectly crystalline; *selenite* is a transparent, highly crystalline mass; *satin gypsum* is fibrous and crystalline; and *alabaster* is pure white, and translucent. Gypsum occurs both in old and new formations, but principally in the new red sandstone, and in the tertiary beds, or those above the chalk. It is mined in various localities in England, and extensively quarried at Montmartre near Paris, whence it has derived its ordinary name of plaster of Paris. Calcined, pulverised, and mixed with water, it is run into moulds, forming stucco images, mouldings, and ornamental fronts for buildings. It is also used for stereotype and pottery moulds, and for medals and casts of various kinds. Mingled with a certain percentage of quicklime, it makes an excellent mortar; its virtues as a fertiliser have been also greatly extolled.

Some of the English gypseous alabasters, such as those of Derbyshire and Staffordshire, stand the turning-lathe

well, and are accordingly formed into jars, vases, and other mantel-piece ornaments. The finest specimens, however, are found near Volterra in Tuscany. These are of a pure white colour and granular texture, and when cut and polished, outrival the finest Carrara marble, from which they are, however, readily distinguished by their softness and liability to tarnish. A large trade in alabaster-work is carried on in Florence, Leghorn, and Milan, where the material is fashioned, partly by the chisel, and partly by the turning-lathe, into statues, vases, lamps, boxes, stands for time-pieces, and other ornamental objects. All sculptures of alabaster should invariably be kept under a glass-shade, as a few months' exposure destroys at once their purity of colour and marble translucency.

Coral.

Coral, or coral-stone, is another calcareous material of commerce, which deserves to be noticed. Being entirely the secretion of certain marine animalcules, it is pretty nearly a pure carbonate of lime, and occurs in the warmer latitudes of the Pacific in vast barriers and reefs, often from fifty to one hundred feet in thickness, and from a few miles to hundreds of leagues in linear extent. Selecting for their residence some submarine ledge of rock, the animalcules begin to ply their vocation, increase, and spread, ever adding to their calcareous secretions, which by and by come to the surface, when they stop and carry on their operations laterally—thus in time elaborating masses which may well compete with any of the ancient rock-formations. (See ZOOLOGY.) There are numerous varieties



Coral.

of the coral animalcule, each variety forming a coral of different shape, but still of the same substance; and ultimately, when indurated by ages, of the same solid and rocky-like consistence. Coral-rock is occasionally employed in the settlements of the South-sea islands as a building-stone, volcanic forces having thrown beds of it several hundred feet above the present sea-level.

The recent branching-corals are solely in request for ornamental purposes—their value depending upon the size, solidity, and colour of the specimen. Black and red varieties are the most highly prized—portions of Sicilian coral having been known to bring as much as eight or ten guineas per ounce. The price, however, is extremely variable, other portions of the same mass selling for less than a shilling a pound. Regular coral-fisheries are established in the Straits of Messina, on the shores of Majorca and Iviza, the coast of Provence, and in other parts of the Mediterranean. Abundant supplies are also obtained from the Red Sea, the Persian Gulf, the coast of Sumatra, &c. The mode of fishing coral, as practised in the Mediterranean, is extremely primitive, but curious:—Seven or eight men go in a boat commanded by the proprietor; the caster throws the net or dredge used to tear up the coral from the bottom of the sea, the rest of the hands work the boat and help to draw the net. This is composed of two beams of wood tied crosswise, with leads fastened to them to sink them: to these beams is fastened a quantity of hemp, twisted loosely round, and intermingled with some loose netting. In this condition, the machine is let down into the sea, and when the coral is pretty strongly entwined in the hemp and nets, they draw it up with a rope, which they unwind according to the depth, and which it sometimes requires half-a-dozen boats to draw.

ARGILLACEOUS SUBSTANCES.

Under this section we include all those substances in which clay (*argilla*) is a prevailing ingredient—as the common clay of the brick and tile maker, the prepared clay of the potter, fuller's-earth, and the slate now so generally used for roofing. Argillaceous compounds occur in every formation, from the lowest slate, through the shales and fire-clays of the coal-measures, up to the plastic clays of the tertiary and superficial deposits. In the earlier formations, they are compact, slaty, and somewhat crystalline; as we ascend, they become dull and merely laminated; while in the more recent deposits lamination disappears, and we are presented with mere tenacious masses, void of anything like structural arrangement. As discovered by Davy, *aluminum* is the metallic basis of pure clay or alumina (oxide of aluminum); but neither the metal nor its oxide is ever found in nature in a state of absolute purity. Sand, lime, magnesia, metallic oxides, and other ingredients, are less or more incorporated with all natural clays; and according to the characters so derived, do they acquire their peculiar values.

Clay.

The common superficial clay, which is so liberally spread over our island, must be familiar to every one. It is of various colours—yellow, red, or bluish; more or less mixed up with sand and fragments of rock; and when softened with water, becomes plastic and tenacious. It is this variety that is ordinarily used for the manufacture of bricks, roofing and drain tiles, chimney-tops, water-tubes, and the coarser sorts of earthenware. For these purposes, it is broken down, partly by exposure to the weather, and partly by the pug-mill, kneaded with water, and freed from the grosser impurities, after which it is beat up into the desired consistency, passed through moulds, dried so far in the atmosphere, and then burned in *clamps* or in kilns. For bricks, slabs, crucibles, &c., which have to resist the action of fire, some of the coal-measure clays are generally had recourse to; these, from their greater purity, and a certain percentage of silica, being susceptible of a more thorough burning. In this case, the raw material requires to be mixed, but generally in connection with the working of coal or ironstone. In England, the Windsor, Stourbridge, and Welsh fire-clays are esteemed the best—the latter yielding those large square slabs employed in the construction of drying-kilns, brewers' coppers, sugar-boilers, furnaces, &c. In the preparation of fire-clays, greater labour and care are necessary—the crude material being generally ground under heavy stone or cast-iron wheels, and in most instances requiring artificial admixture.

Pipe-clay, potters-clay, and porcelain-clay, are but technical names for pure varieties of well-prepared specimens of the same substance. We have seen that common brown ware can be made from ordinary clay; but when the finer varieties of white ware or china are attempted, not only finer clays must be sought, but even these must be mixed with a certain proportion of calcined flint or silex. One of the finest varieties of aluminous earth is the china-clay of Devon and Cornwall, or the *kaolin* of the Chinese. This is a decomposed felspar—one of the constituent minerals of granite—which has accumulated in vast quantities in certain localities, having been no doubt washed down by rains from the weathered and exposed surface of granitic

rocks. At one time, the use of this substance was unknown in England; but now about 38,000 tons—worth about £50,000—are annually exported from the south of England, for the Staffordshire potteries, and for the manufacture of mosaic tesseræ, buttons, artificial gems, and the like. The best pipe-clay is obtained from Poole in Dorsetshire, and the isle of Purbeck; it is employed in the manufacture of tobacco-pipes and fine pottery, and also sometimes used for the fulling or scouring of woollens.

Fuller's-earth.

Fuller's-earth is a soft, dull, unctuous kind of clay, usually of a greenish-brown colour. It is dug in various parts of England, particularly in Buckingham, Surrey, Hampshire, and Bedfordshire, the lighter-coloured beds being the most esteemed. It is used in the fulling of cloth, from its property—a property common to all soft aluminous minerals—of absorbing oil and grease. At one time it was deemed of so much importance to the national trade in woollen, that its exportation was prohibited; but now soap is chiefly used instead, and fuller's-clay has fallen in importance. What the present consumption may be, it is impossible to say; but about forty years ago not less than 7000 tons were annually made use of. Although denominated a clay, it is essentially composed of silicious earth, only about a fourth part being pure alumina; and if the proportion of clay were much greater, it would become too tenacious to be worked by the fuller. Every clay that is of an unctuous or saponaceous quality, will answer in some degree the purposes of fulling, but not so well as proper fuller's-earth, which is distinguished from common clay by its falling to pieces in water with a slight crackling noise, instead of making a paste with it as clay does.

Ochre.

This is a painter's term for a native earthy mixture of alumina, silica, and oxide of iron. It is found of various hues, but chiefly of a yellow or reddish-brown, and is employed as an ingredient in painters' colours, and in the polishing of metal articles. It is obtained from various places, particularly from Shotover Hill, near Oxford; from the coal-measures of the east of Fife; and from Italy. The quantity raised in Britain is unknown, but about 5000 hundredweights are said to be annually imported. In general, ochre is obtained by a rude sort of mining, and requires to be prepared for use by trituration and elutriation.

Clay-slate.

Clay-slate, of which roofing and writing slate are the most familiar examples, is very extensively diffused, and as extensively made use of in the British Islands. It belongs to one of the lowest or oldest formations, is essentially composed of alumina and silex, has a peculiarly fissile structure, and is usually of a dark lustrous blue, bluish-green, or purplish colour. Like all mixed rocks, the chemical composition of clay-slate varies considerably. The following is given as the analysis of a common Scotch variety: Silex, 50; alumina, 27; oxide and bisulphuret of iron, 11; potash, 4; magnesia, 1; carbon, a trace; and water, 7. The principal quarries are in Wales, where they give employment to nearly five thousand hands; in the north of England and west of Scotland; the most extensive being in Caermarthen near Bangor, in Borrowdale in Cumberland, and at Easdale and Ballahulish in Argyleshire. The beds of clay-slate are often of great thickness, but only certain portions are sufficiently compact to be of commercial importance. The chief consumer of this material is the slater, though considerable quantities are also used as pavement in cellars and warehouses, for shelves in dairies, for the construction of cisterns, and the like. The finer-grained varieties are polished for school-slates and slate-pencil; and those of attractive colours are now manufactured into flower-pots, vases, fancy-tables, and other ornamental objects.

Clay-slate is invariably quarried; and here it must be observed, that the splitting of the rock does not take place in the direction of the bed, but at a considerable angle to the plane of stratification. This peculiar structure is known as *cleavage* (see GEOLOGY), and seems to have been superinduced long after the deposition of the strata. It is totally different from *lamination*, which allows certain sandstones and shales to be split into thin slaty bands, and which is a natural structure of deposition, always parallel to the plane of stratification. A piece of slate being split to the desired thickness, it is next squared by a knife, or cutting-edge of steel, the slate being held over a similar cutting-edge or anvil. Polishing is performed by sand, emery-powder, and water; and some varieties of slate stand to be sawn, planed, and turned by tools differing little from those of the joiner. The following is generally given as a test of the fitness of slates for roofing and other external purposes: —Lay one in an oven till perfectly dry; weigh it, and then immerse it in water for some time. When taken out, wipe it carefully with a dry cloth, and weigh it again. Those slates which have acquired the least additional weight, and consequently have absorbed least water from being the least porous, are the fittest for roofing. Good slates should be thin, dense, and of a smooth surface. Balance one on the finger, and strike it with a hammer; if the sound is clear, the slate may be considered as firm; if dull, the slate is less dense, and should be rejected. *Whet*, *polishing*, and other varieties of slate, are treated under the following section.

SILICIOUS SUBSTANCES.

Silex or silica is one of the most important and most generally diffused of the mineral ingredients that enter into the composition of the rocky crust of the globe. Rock-crystal, quartz, chalcedony, and flint, may be regarded as nearly pure silica; and all the varieties of sandstone, quartz-rock, and granite, are in a great measure composed of it—many sandstones, for example, being pure granular quartz or silica, with a slight argillaceous cement. As in the case of the alkaline earths, it has been shewn that silica is an oxide, the basis of which is *silicium* or *silicon*—a substance more closely allied to boron than any other substance, but probably not metallic.

Quartz—Rock-crystal.

Quartz and quartz-rock, though of importance as forming the bases of other rocks, are of themselves of no great commercial value. Pounded quartz, as stated under FICTILE MANUFACTURES, enters largely into the composition of Chinese porcelain, performing the same part as calcined flint in the wares of England. The purer varieties of rock-crystal are occasionally cut as ornamental stones; and of late the transparent and colourless varieties have been pretty generally adopted by opticians as spectacle lenses. Their extreme hardness renders them more durable than glass, and less liable to be scratched, while they are altogether cooler and more agreeable. The so-called Brazilian pebble, used for this purpose, is of pure silica, and is sometimes found in crystals as large as a cocoa-nut. Quartz, in its crystalline forms, constitutes several of the 'Precious Stones,' or gems, and will be further treated under that head.

Flint.

The common nodular flints found in the chalk-formation are nearly pure silica, exhibiting but a trace of alumina, oxide of iron, and lime. The formation of flint within a mass so different in composition as chalk, is still, in some respects, an unsolved problem in geology. It occurs in nodular masses of very irregular forms and of variable magnitude, some of these not exceeding an inch, others more than a yard in circumference.

Although thickly distributed in horizontal layers, they are never in contact with each other, each nodule being completely enveloped by the chalk. Externally, they are composed of a white cherty crust; internally, they are of gray or black silex, and often contain cavities lined with chalcedony and crystallised quartz. When taken from the quarry, they are brittle, and full of moisture, but soon dry, and assume their well-known hard and refractory qualities. Flints, almost without exception, enclose remains of sponges, alcyonia, echinida, and other marine organisms, the structures of which are often preserved in the most delicate and beautiful manner.

The uses of flint are various: calcined and ground to a powder, it is used in the manufacture of the finer sorts of pottery and porcelain; it also enters into the composition of flint-glass; is employed in the preparation of certain kinds of soap; and before the invention of the percussion-cap, gun-flints were in universal use. Flints also form excellent building materials, because they give a firm hold to the mortar by their irregularly rough surfaces, and resist, by their hardness, every vicissitude of weather. The counties of Kent, Essex, Suffolk, and Norfolk, according to Dr Ure, contain many substantial specimens of this sort of masonry. The reduction of flint to economical uses is extremely simple. We have stated how it is prepared for the potter and glass-blower (FICTILE MANUFACTURES); the formation of gun-flints is a process strictly mechanical, and depends wholly on dexterous manipulation.

Sandstones.

Sandstone, or freestone, as it is sometimes called, occurs in innumerable varieties, differing in colour, in composition, fineness of grain, and compactness. Thus, we have some red, from the presence of peroxide of iron; some silvery and glistening, from the presence of minute scales of mica; others white, yellow, and mottled; and some almost jet-black, from the presence of bituminous or carbonaceous matter. As to mineral composition, there is no other class of rocks so varied; for though quartz grains give to them their family character, clay, lime, mica, carbon, iron, and the like, mingle with them so capriciously, that it is impossible to find any two strata of sandstone exactly of the same composition. Again, their texture is equally if not still more varied; in some the grains being as large as pease, in others quite impalpable; some being so soft and friable as to be rubbed down by the hand, and others so hard and compact that nothing but the chisel of the stone-cutter can touch them.

In England, where bricks form the more available material for the construction of houses, there are comparatively few freestone-quarries of much importance. Those of Portland Isle, which have furnished the stone for St Paul's and other public buildings in London, those of Bath, and of Gateshead Fell, near Newcastle, are the most extensive and valuable. In Scotland, freestone of excellent quality is to be found in most localities, and consequently it is the prevailing architectural material. The best strata are those belonging to the coal-formation—such as are quarried in the neighbourhood of Glasgow, Linlithgow, Edinburgh, and in several parts of Fifeshire. The principal buildings of the New Town of Edinburgh are constructed of this material. Good building sandstone is also obtained from the old red formation, such as is quarried at Kingoodie, and other places near Dundee, the rock being at once exceedingly durable, and producing blocks of any dimensions.

Many sandstones are likewise used as pavement, those being sought for that purpose which are at once compact and thin—bedded or schistose. By far the most valuable of this kind are the Forfarshire gray micaceous flagstones, now so generally employed as foot-pavement in all our large towns. A very extensive trade in these is carried on at Arbroath and Montrose, the flagstones being now dressed and hewn by machinery at the quarries. Another excellent material, still more durable, but exceedingly hard and refractory, is also obtained from Caithness. Pavement of average quality is likewise obtained from the coal-measures; but being of a softer and more absorbent texture, is not so well adapted for outdoor purposes. All these beds are highly fissile or schistose, occurring in laminæ or layers of from one to fourteen inches in thickness; and thus accounts for the fact, that at one time the thinner sorts were used for roofing, under the name of *tile-stones*, or gray-slate.

Besides building and paving, several sorts of sandstone are employed for grindstones, millstones, whetstones, and the like. Thus the quarries of Gateshead Fell, situated on the *millstone grit*, or quartzose sandstones of the lower coal-measures, furnish the grindstones known in all parts of the world as 'Newcastle grindstones.' Good millstone and whetstone beds are found in various other places, as are also varieties fit for the wheels of glass-cutters and cutlers. The stones chiefly used in Sheffield are procured at Wickersley in Yorkshire. The celebrated *burr* millstones of France are obtained from the upper fresh-water silicious limestones of the Paris basin, and are not strictly sandstones, in the usual acceptation of that term. A close grit, containing a certain amount of talc, is quarried at Coxgreen, in the neighbourhood of Newcastle, and highly prized as a firestone in the erection of glass-furnaces.

Sand.

On narrowly inspecting the immense masses of sand scattered over the surface of the country, it will be found that the great bulk of it is composed of silicious particles, evidently derived from decomposed quartz-rock, granite, sandstone, and the like. As might be expected, most sands are mingled with clay, lime, and other earthy impurities; and it is according to their silicious character, and degree of purity from earthy ingredients, that they become of value in the arts. Thus sharp, well-sifted sand is an indispensable ingredient in well-prepared mortar, without which the builder, the plasterer, and fresco-painter could not proceed a single step: the commoner sorts are widely used in paving, in the construction of ovens, kilns, annealing furnaces, and the like, where heat is wished to be retained; and some peculiar varieties are much used in the preparation of moulds for the casting of iron, brass, and other metals. Good silicious sand is an indispensable ingredient in all sorts of glass, now one of the most important manufactures in the civilised world. The most valuable sands for this purpose are those of Aumont, near Senlis, in France, and those of the Isle of Wight, and of Lynn, in Norfolk, in England.

Granitic Rocks.

This term may be considered as embracing not only the true igneous granite, but the gneissose and mica-slate rocks, which, though stratified, partake of the same mineral character, and are usually associated with it. In all of them, silica is a predominant ingredient, imparting those hard and durable qualities which render them of economical importance. Ordinary granite is a crystalline compound of quartz, felspar, and mica; but other minerals, such as hornblende, hypersthene, &c., occasionally mingle with it, thus producing a number of varieties. The small-grained grayish granite of Aberdeen is essentially a compound of quartz, felspar, and mica; that of Peterhead is the same compound, rendered red by the oxide of iron contained in the felspar crystals. Granitic compounds are very widely distributed, forming the fundamental rock of our principal mountain-chains. The Grampians in Scotland, the Cumberland and Cornish hills in England, the Wicklow Mountains in Ireland, the Pyrenees in Spain, the Dofrefeld in Norway, the Ural in Russia, the Abyssinian and other African ranges, and the Andes in South America, are all less or more composed of rocks partaking of a granitic character.

The economical uses to which granitic rocks are applied are by no means unimportant. Compact granite, from its extreme hardness, is largely employed in the construction of docks, piers, light-house foundations, bridges, and other structures where durability is the main object in view. Waterloo Bridge in London, the Liverpool and other English docks, are built of granite. It is the ordinary building-stone in Aberdeen, and is largely used in the metropolis for paving. The Pyramids, though internally constructed of limestone, are externally coated with granite. Pompey's Pillar, and other ancient Egyptian structures, are composed of it; the column of Alexander, and the pedestal of the colossal statue of Peter the Great, in the Russian capital, as well as several monumental monolithes in other countries, are also of granite. Within these few years, the granite of Aberdeenshire has been brought into use as an ornamental stone; and machinery has been erected, both at Aberdeen and Peterhead, for the purpose of polishing it like marble, to which many prefer it, for chimney slabs, vases, pedestals, pillars, &c. When uniform and compact in grain, it is susceptible of a very high polish; and has this advantage over marble, that it is not easily stained or scratched, nor at all acted upon by acids.

Serpentine, or the magnesian rock generally so called, is one of very varied composition and quality. The noble serpentine of the mineralogist is a green translucent rock, rather soft, but susceptible of a good polish; and if found in sufficiently large blocks, would make not a bad substitute for marble. We have before us a specimen of a beautiful leek-green variety from New Zealand, where it is said to occur eight or ten feet thick, and capable of being raised in blocks of any size. Should this be the case, the houses of our brethren who have made these islands their adopted home need be in no lack of interior decorations. Potstone, the *lapis ollaris* of the ancients, is another granitic product, easily worked into form, and formerly used for culinary vessels; whence its common designation. *Jade*, sometimes called *nephrite*, from its supposed medicinal virtues, is another dark leek-green mineral of the same family. It contains a larger amount of silica than the true serpentine, which it greatly resembles. In New Zealand and the Indian Archipelago, it is fashioned into hatchets, edge-tools, and other implements.

Mica—Talc—Asbestos.

Mica, talc, asbestos, and other kindred minerals which are the products of the granitic and primary rocks, may be appropriately considered in this place. The silvery-looking, scaly substance which occurs in ordinary granite is mica, so called from its glistening aspect. It is sometimes found in crystals more than a foot square; and when of this size, is split into thin plates, and, from its transparency, used in certain cases as a substitute for glass. It stands a higher degree of heat, without splintering, than glass, and is well adapted for ship-lights, not being liable to fracture during the firing of cannon. The large sheets exposed for sale by the mineral dealers are generally brought from Siberia; hence the term, *Siberian glass*.

Talc, when crystallised, has much the same appearance, but on trial will be found to be less transparent, softer, and non-elastic. Talc-slate, the other form in which this mineral occurs, is a massive mineral, breaking up in tabular fragments; it has a white streak, and greasy or soapy feel. It is employed in the porcelain and crayon manufactures, and is used as a marking material by carpenters, tailors, and others.

Asbestos, or amianthus, is a soft mineral, occurring in separate filaments of a silky lustre, and consisting essentially of silica, magnesia, and lime. When steeped in oil, it may be woven into cloth, which is incombustible, and may therefore be purified by fire; hence the terms amianthus (*amianthus*, undefiled) and asbestos (*asbestos*, unconsumable). Cloth of this kind was used by the ancients to wrap the bodies of the dead about to be burned, to prevent their ashes being mixed with those of the funeral pile. In the United States of America, asbestos is sometimes used as a lamp-wick.

Basaltic Rock.

Under this head we include all the basalts, greenstones, whinstones, and traps, which make up the sum of the igneous rocks of the secondary formations. They are essentially silicious—quartz, hornblende, hypersthene, augite, and so forth, entering largely into their composition. Some of the basalts and greenstones dress well under the hammer, and though of a dingy colour, make an excellent building-stone, their durability being equal to that of granite itself. Ordinary greenstone, or whinstone, is a very valuable rock in many districts of Scotland, where it furnishes material at once for houses, fences, drains, and roads. Indeed, no rock is better adapted, or more extensively used, for causewaying, and for macadamised roads it is unrivalled. We have seen some ornamental pedestals in basalt which took on a pretty fair polish; and an elaborately carved Buddhist idol, of considerable size, now in the museum at St Andrews, is of the same material. Some of the trap-rocks stand fire to perfection, and this has suggested their use as oven-soles, where such varieties can be procured.

Volcanic Products.

The mineral products ejected from volcanoes are chiefly lava, obsidian, pumice, scoriæ, and a light impalpable dust, in all of which silica and alumina are the main ingredients. Some of the compacter sorts of *lava* are hardly to be distinguished from the trap-rocks of the secondary formations, and may consequently be employed for the same economical purposes. *Obsidian*—so named, according to Pliny, from one Obsidius, who first brought it from Ethiopia—is a true volcanic glass, of various colours, but usually black, and nearly opaque. In Mexico and Peru, it is occasionally fashioned into adzes, hatchets, and other cutting instruments, or into ring-stones. So closely does it resemble the slag of our glass-furnaces, that in hand specimens it is almost impossible to distinguish the natural from the artificial product. It consists chemically of silica and alumina, with a little potash and oxide of iron. *Pumice*, a well-known volcanic product, is extremely light and porous, and of a fibrous texture; it is harsh to the touch, is usually of a grayish colour, and has a shining pearly lustre. Like obsidian, it is principally composed of silica and alumina, with traces of potash, soda, and oxide of iron. Pumice is quarried and exported in large quantities from the Lipari and Ponza islands, off the coast of Sicily. It is used for polishing metals, glass, marble, wood, ivory, and also in the smoothing of parchment and vellum. *Pozzuolana*, already described under FICTILE MANUFACTURES, is another volcanic product, which has been long and largely used in the preparation of hydraulic cements.

Tripoli, &c.

We include under this head several silicious earths and slates extensively employed in the polishing of metallic surfaces. The most familiar of these are—tripoli (so called from Tripoli in Barbary, whence it was originally procured), polishing-slate, semi-opal, and some of the porcelain earths. The uses of these substances are well known: it is their peculiar origin that confers on them an especial scientific value and interest. It has been established by Ehrenberg, that these and several other rocky masses are not the results of ordinary deposition, but an aggregation of the silicious shells of the minutest animalcules. This is a curious fact: the remains of creatures, individually invisible to the naked eye, forming rocks which, in the course of time, were to figure in the economical applications of the human race! On analysis, a hundred parts of tripoli are found to contain

upwards of eighty of silica, the remainder consisting of alumina, oxide of iron, and water. The *polirschiefer*, or polishing-slate of the Germans, found at Bilin in Bohemia; and the *berg-mahl*, or mountain-meal of the Swedes, said to be mixed with bread in times of scarcity, are substances of similar origin and use. Another species of infusorial earth is said to be occasionally eaten by the North American Indians; it is probably the same as the European mountain-meal. The well-known *rotten-stone* of Derbyshire and other localities is more argillaceous than silicious; it is largely used for giving the final polish to metals, glass, marble, and precious stones.

SALINE SUBSTANCES.

Under this section we comprehend such products as rock-salt, alum, saltpetre, borax, and the like, which are found either as native salts, or are procured by artificial processes from certain mineral substances with which they are combined in nature. Some of these salts are of vast economical importance, and appear to be as indispensable to the progress of civilised life as either coal or iron.

Rock-salt.

The common culinary salt of everyday use is chemically a muriate of soda, or, more strictly, a chloride of sodium, every hundred parts of which are composed of sixty chlorine and forty soda. It exists abundantly in sea-water, constituting more than a thirtieth part of its weight; it is discharged by salt or brine springs—which arise from different geological formations, and are situated in different countries—to the extent of from 20 to 30 per cent.; and it is found in various degrees of purity in beds and irregular masses, from 20 or 30 to more than 120 feet in thickness. Native chloride of sodium is never found in a state of absolute purity, but is always less or more combined with certain salts of lime, magnesia, soda, iron, and alumina; to free it from these impurities, and render it fit for culinary purposes, is the duty of the salt-boiler and refiner.

At one time, salt was largely, and is still to some extent, derived by evaporation from sea-water, by the following simple process:—A reservoir is erected near the sea, into which, at high-water, supplies are taken by means of a pipe extending a good way down the beach. The pipe is generally placed near the low-water mark, in order to get the water from a point as far from the surface as possible, so that it may be the more impregnated with salt, and require less boiling. The pans are built on a range on both sides of the reservoir, from which the water is pumped into them after the impurities have settled. The pans are shallow vessels, made of sheet-iron, about twenty feet long, and twelve broad, with a furnace below. These are contained in a small low-roofed house, the covering of which is of deals, with an opening at the meeting of the roof and the wall, to allow the vapour to escape. When the water is boiling, a little bullock's blood is put into the pan, which brings the impurities to the surface, and allows of their being skimmed off. As the water boils down, more is pumped in; and this process is repeated before the salt is finally drawn. From a pan of 1800 gallons, fifteen or twenty bushels, of fifty-six pounds each, are obtained in this manner, the process requiring about twenty-four hours. The salt is at first very light and floury in proportion to its bulk, and in this state is most appreciated. A still finer article resolving into large crystals—bay-salt—is made with a low fire, and when a longer time is allowed in the evaporation. For use at table, the salt is refined, and usually run into large lumps. The water which remains after the salt is crystallised, called the *mother-water*, contains a considerable quantity of the chloride of magnesium or bittern, chloride of sodium, and sulphate of magnesia.

The process of procuring salt from sea-water is now all but abandoned in Britain, and is only had recourse to in some southern and tropical countries, where the arts of life are still in a rude and primitive condition. The supply is mainly obtained from brine-springs, such as those of Droitwich in Worcestershire; and from the mineral rock-salt, which abounds in the new red sandstone and upper secondary formations. This important mineral product occurs in Cheshire and Worcester in England, at Altemonte in Calabria, Halle in the Tyrol, Cardona in the Pyrenees, Wieliczka in Poland, and in several districts of North America. As brine-springs always issue from saliferous deposits, and are doubtlessly derived from the solution of the solid masses by subterranean waters, we shall restrict our description to the solid rock-salt, taking the mines of Cheshire as a sufficiently illustrative example. These mines, together with the brine-pits of Worcester, not only supply sufficient salt for the consumption of almost the whole of Britain, but furnish an article of export to the extent, perhaps, of half a million tons annually.

In Cheshire, the rock occurs in large quantities in the condition of an impure muriate of soda. The appearance of the rock-salt is by no means of that brilliant character, nor has it the delicate transparency and bright reflecting surface which the reader may perhaps suppose characteristic of it. It is usually of a dull red tint, and associated with red and palish-green marl; but it is still not without many features of great interest; and when lighted up with numerous candles, the vast subterranean halls that have been excavated, present an appearance richly repaying any trouble that may have been incurred in visiting them. At Nantwich, and the other places in Cheshire, where the salt is worked, the beds containing it are reached at a depth of from 50 to 150 yards below the surface. The number of saliferous beds in the district is five; the thinnest of them being only six inches, but the thickest nearly forty feet; and a considerable quantity of salt is also mixed with the marls associated with the purer beds. The method of working the thick beds is not much unlike that of mining the thicker seams of coal. The roof, however, being more tough, and not so liable to fall, and the noxious gases—with the exception of carbonic acid gas—totally absent, the works are more simple, and are far more pleasant to visit. Large pillars of various dimensions are left to support the roof at irregular intervals, but these bear only a small ratio to the portion of the bed excavated, and rather add to the picturesque effect in relieving the deep shadows, and giving the eye an object on which to rest. The intervening portions are loosened from the rock by blasting; and it may be readily understood that the effect of the explosions heard from time to time, and re-echoing through the wide spaces, and from

the distant walls of rock, impart a grandeur and impressiveness to the scene not often surpassed. The great

charm, indeed, on the occasion of a visit to these mines, even when they are illuminated by thousands of lights, is chiefly owing to the gloomy and cavernous appearance, the dim endless perspective, broken by the numerous pillars, and the lights, half disclosing and half concealing the deep recesses which are formed and terminated by these monstrous and solid projections. The descent to the mines is by a shaft, used for the general purposes of drainage, ventilation, and lifting the miners and produce of the mine. The shafts are of large size in the more important works, and the excavations very considerable, the part of the bed excavated being in some cases as much as several acres. Over this great space, the roof, which is twenty feet above the floor, is supported by pillars, which are not less than fifteen feet thick. The Wilton mine, one of the largest of them, is worked 330 feet below the surface; and from it, and one or two of the adjacent mines, upwards of 60,000 tons of rock-salt are annually obtained, two-thirds of which are immediately exported, and the rest is dissolved in water, and afterwards reduced to a crystalline state by evaporating the solution. The modes of working rock-salt are much the same in all countries; while the fineness and purity of the manufactured material depend upon the rapidity with which the brine is evaporated, and the nature of the clarifying agents employed. The uses of salt, whether obtained from sea-water or from mineral products, are so numerous and so well known, that it would be almost superfluous to attempt their enumeration. From its use as a simple condiment, through all its applications in the arts, up to the manufacture of soda from its substance, salt is one of the most important of natural products.

The formation of rock-salt is a subject which has much engaged the attention of speculative geologists. Being found regularly interstratified with sandstones and other beds, it becomes evident that the formation has taken place in some way consistent with the ordinary processes by which sedimentary rocks in general have been formed. The reigning theory as to the origin of salt is, that it is washed out of the land in the course of disintegration, and carried by rivers into the sea, or into detached lakes, all of which, as is well known, are charged with salt, in consequence of evaporation carrying off only the pure water, and leaving the infused matters behind. It is a chemical law affecting water liable to receive such contributions of salt, that it cannot retain in solution more than a certain quantity: so soon as this amount is attained, the salt begins to fall to the bottom. Now, if a group of detached lakes, existing in the era of the New Red Sandstone, had received charges of salt beyond what the water was fitted to retain in solution, depositions like what we find in Cheshire would unavoidably follow; and these would be liable to be covered over with deposits of mud and sand, as casual circumstances might determine. Estuaries cut off by convulsions of the land, and then dried up, would also become basins for the deposit of salt; and probably some of our salt-beds originated in that manner.

Alum.

This is a well-known earthy salt, found native only in small quantities, but very largely manufactured from certain argillaceous strata, generally distinguished as alum-clays and shales. It is composed of alumina, sulphuric acid, potash, and has a sweet and astringent taste, and is a powerful styptic. It is much used in dyeing and in calico-printing, in consequence of the attraction its base has for colouring-matter; it is also used in lake colours, in leather-dressing, in the preparation of paper-pastes, in clarifying liquors, and by candlemakers to harden and whiten the tallow.

Native alum being too scanty a product to be used for any of these purposes, it has become the duty of the chemist to prepare it artificially—either from mineral substances which contain the elements of alum, or by mixing these elements together, so as to lead to their chemical combination. Thus, at Hurlett and Campsie, near Glasgow, it is manufactured from certain of the coal-shales, and at Whitby, in Yorkshire, from strata of alum-slate belonging to the lias-formation; while at Newcastle and in France it is artificially prepared by mixing clay, sulphuric acid, and potash—soda or ammonia being sometimes substituted for potash. In the former case, if the crude ore is hard and slaty, it requires to be calcined and exposed to the air, in order to facilitate its solution in water; if soft, crumbling and efflorescent, calcination is dispensed with. This being effected, it is next steeped till the ore is spent; the liquid is then pumped off, boiled, and ultimately crystallised by adding the potash, without which, or some other alkali, sulphate of alumina does not crystallise. When alum-shale contains sulphate of iron (copperas or green vitriol), which is the case at Campsie, this salt is removed from the concentrated solution before adding the potash to obtain the alum. In the second or chemical mode of manufacture, calcined Cornish clay and sulphuric acid are combined to form the sulphate of alumina, to a solution of which the sulphate of potash is added to induce crystallisation. These different ingredients are allowed to remain at rest in circular vessels, where the alum gradually crystallises round the sides, shooting forth large crystals towards the centre, where the mother-liquor (or uncrystallisable portion) remains. The alum thus produced requires to be further fined or *roched*—that is, dissolved by the action of steam, and again crystallised for the market.

In both of the methods above described, an alkali is used to induce crystallisation; but as the sulphate of alumina is the sole efficient agent in the arts, a process has been invented to produce a 'patent alum,' having all the properties of common alum, but without containing potash. 'In making this alum,' says Mr Dodd, 'sulphuric acid and Cornish clay are used as in the other case; but the clay is used in greater proportion, so as to form a thick paste. This paste is placed in a heated trough, where the moisture is so far evaporated as to convert the mass to the form of a dry earth. From the trough it is removed to tanks, where water is employed to dissolve it; and while in the liquid state, the composition is acted upon by an agent intended to remove any iron that may be in the clay—this being the only contained ingredient which is injurious to the alum. The agent employed combines with the iron existing in the clay, and forms with it Prussian blue. This pigment is allowed to subside, and the remaining liquor, being a solution of sulphate of alumina, is boiled till all the water is driven off. The solid residue is formed into cakes an inch or two in thickness, and in this form it comes into the market. Instead of being a crystal, it is an opaque earthy solid, differing from common alum in containing no potash, but possessing in common with it the properties which render it valuable in the arts. As the Prussian blue is procured in far too large a quantity to be allowed to remain in that state, it is restored again, by chemical means, to the form which it before presented, ready to be again used in making more alum.'

Of the alums manufactured in other countries, the *roche* (so called from Roccha in Syria) is imported from Smyrna, and the *Roman* prepared at La Tolfa, near Rome—either of which brings fully double the price of the British manufacture. Alum is also largely prepared in China, whence India obtains her main supply.

Nitrate of Potash.

This is the *saltpetre* of ordinary language—a salt composed of nitric acid and potash. It is of very varied utility, being used in the manufacture of gunpowder, signal-lights, nitric and sulphuric acids, and in dyeing, metallurgy, curing of meat, and in medicine. The sal-

prunella of the shops is the ordinary saltpetre purified and moulded into cakes and little balls. Our main supply of saltpetre is derived from Bengal, where it exists in the soil, and from which the rough nitre or crude saltpetre of commerce is obtained by washing, evaporation, and crystallisation. From 10,000 to 15,000 tons of this salt are annually imported into Britain. In France, Germany, and other continental countries, the salt is produced artificially on what are called *nitriaries*, or nitre-beds.

Nitrate of Soda.

This salt, sometimes known by the name of cubic nitre, possesses properties similar to those of saltpetre, differing chiefly in being more pungent in taste, more soluble in cold water, and more inclined to attract moisture from the atmosphere. It differs also in the form of its crystals—these being of a rhomboid form, while those of saltpetre are six-sided prisms. It is obtained almost wholly from South America, where it occurs in immense deposits in the high districts of Atacama and Tarapaca in Peru. Indeed, according to Darwin, a great proportion of the surface of the southern regions of South America consists of *salinas*, or salt-plains, from which common salt, and the sulphates and nitrates of soda, might be procured in any quantities—these occurring sometimes as an efflorescence, sometimes in crystallised strata, but oftener mingled with clay, sand, and other earthy impurities. One deposit which he visited in 1835, was full 3300 feet above the Pacific, and consisted of a hard stratum, between two and three feet thick, of the nitrate mingled with the sulphate of soda, and a good deal of common salt. It lay close beneath the surface, and followed, for a length of 150 miles, the margin of a grand basin or plain, which, from its outline, must once have been a lake, or more probably an inland arm of the sea, as iodic salts were abundant in the stratum. This salt was first imported from Iquique in 1830, and so rapidly has its commercial value increased, that, ten years after, about 150,000 hundredweights were shipped for Great Britain alone. In 1835, Mr Darwin found the selling-price at Iquique 14s. per 100 pounds—the main part of the expense being its transport from the mountains on mules and asses. It is principally used as a manure, and as a top-dressing for pasture, its advantages being very perceptible on all but wet plashy soils; it is also used in the preparation of nitric acid, and for many of the purposes to which saltpetre is applied; but, owing to its deliquescent properties, it is not adapted for the manufacture of gunpowder.

Natron.

Natron is a native sesquicarbonate of soda, found as an efflorescence or as deposit in sandy soils in Egypt, Mexico, Hungary, and other countries; hence sometimes called *mineral soda*. At the lakes of Sukena in Africa, this salt is said to form a striated crystalline stratum just below the surface. From these lakes, several hundred tons are collected annually in the dry season, chiefly for consumption in Africa, but sometimes exported to Europe under the name of *trona*. Natron has many of the properties of the two preceding salts, and, according to Herodotus, was employed by the Egyptians in the process of embalming.

Borax.

This compound salt is found native as an efflorescence on the soil, or dissolved in the waters of certain lakes, in Persia and Tibet, in China, Ceylon, and South America. It occurs also in combination with several minerals, and, as might be expected, is given off in solution by hot and thermal springs. It is a compound of soda with a peculiar acid, first isolated by Homberg about the beginning of last century. The acid is now known to be an oxide of an elementary substance, to which the name of *boron* is given (see CHEMISTRY); the acid itself is known by the term *boracic acid*. 'Until the recent discovery of a more advantageous mode of obtaining borax, it was brought to Europe,' says Parnell, 'in considerable quantities from the East Indies. It was imported in small dirty crystalline masses called *tincal*, which contain scarcely more than half their weight of pure borax—the remainder consisting chiefly of a peculiar saponaceous combination of soda with a fatty acid. The salt was never termed borax till purified by some such process as the following:—The crude salt, being placed in proper pans, is covered with cold water to a height of two or three inches above its surface, and allowed to stand for some hours. Recently slaked lime is then added to the amount of one part to four hundred parts of tincal; the mixture is thoroughly stirred, allowed to stand for twelve hours, again strongly agitated, and the troubled supernatant liquid decanted. The liquor is not thrown away, but preserved to wash the impure borax; the solid matters held in suspension being first separated by subsidence and decantation. The washing is continued with the same liquid, clarified by subsidence as often as applied, until it is no longer rendered turbid. In this way, a great portion of the fatty matter may be washed away as an insoluble soap of lime. The salt thus purified is dissolved in two and a half parts of boiling water, and mixed with a solution of chloride of calcium, containing two parts of that salt to one hundred parts of tincal. A precipitate is thereby produced, consisting chiefly of the insoluble soap of lime; the liquor is separated from the precipitate by filtration, and evaporated down to a density of 1·14 or 1·16. It is then run off into crystallising vessels, and cooled very gradually to obtain large crystals.' Such, with some slight variations, was the mode of preparing borax from tincal.

Tincal, however, is now no longer the European source of the salt, which is largely and economically obtained from the boracic lagoons of Tuscany. These lagoons may be ranked among the wonders of the age, and are unique in Europe, if not in the world. They are situated on the sides of hills, and are supplied with water by the condensation in them of volcanic vapours or *soffioni*, highly charged with free boracic acid, together with borate and sulphate of ammonia, and other saline substances. The soil surrounding these beds of hot water is covered with a saline efflorescence, consisting chiefly of boracic acid, but likewise containing in smaller proportion salts of ammonia, borate, and sulphate of alumina, and persulphate of iron. The presence of free boracic acid in these and other volcanic vapours was ascertained towards the end of last century; but it was not till 1816 that an effectual mode of procuring the crystallised product was discovered. The lagoons are now artificially constructed over the soffioni, the continuous discharge from which more largely impregnates the water with boracic acid, and this solution is still further concentrated by ingeniously applying the superabundant heat of the soffioni to evaporate the water. Passing in this manner from reservoir to reservoir, and from evaporating pan to pan, the solution is ultimately allowed to crystallise; and the acid so obtained packed in barrels for exportation. For the conversion of this crude acid into borax, there are several processes in use, the chief objects of which are to get rid of the ammonia and other natural impurities, and ultimately to obtain the pure salt in large and hard crystals.

The applications of borax in the industrial arts are already numerous. Borax is largely employed by brasiers, silversmiths, and other workers in metals, as a flux; by potters in the formation of a glaze for earthenware and porcelain; by chemists as a reagent in blow-pipe analyses; in the preparation of certain kinds of glass, and generally if its price permitted; in the fabrication of artificial gems; in medicine; and in other minor arts.

Baryta—Strontia.

These are two alkaline earths (see CHEMISTRY) very similar to each other, and indeed, till recently, considered identical. The former is an oxide of barium; the latter, of strontium; neither the metalloids nor their oxides are found in nature. The only two abundant natural compounds of baryta are the sulphate, which occurs crystalline, and the carbonate. Sulphate of baryta, or *heavy spar*, is found in various districts, particularly in Cumberland and Westmoreland; a variety from Derbyshire is provincially called *cawk*. The native forms of strontia are the carbonate and sulphate, both found in a crystalline state. The former occurs abundantly in the lead-mines at Strontian, in Argyleshire—hence the name; the latter is found near Bristol, and associated with native sulphur in Sicily.

Sulphur.

Though sulphur or brimstone be an elementary substance, *sui generis*, and, strictly speaking, does not come under the head of saline substances, yet it may, without much impropriety, be considered in this place, as often occurring in efflorescent salts or crystals. It is a yellow brittle mineral product, found in most parts of the world, but most abundantly in volcanic regions, and in the immediate neighbourhood of burning mountains, such as Etna, Hecla, &c. It occurs either as an efflorescence on the surface, or in masses mingled with clay, ashes, and other volcanic products. Our chief supply is obtained from Sicily, where it occurs in beds of a blue-clay formation; and whence it is imported, as dug from the mines, in square masses or blocks, called rough brimstone. Sulphur is also obtained artificially from the sulphurets of copper, iron, and other metals; but the facility with which native material can be secured, prevents its artificial production from being followed to any great extent.

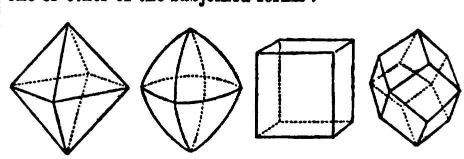
Unlike most other materials of commerce, the formation of sulphur is still going forward wherever volcanic agency is in a state of activity. It appears to be sublimed by the subterranean heat through the crevices and fumeroles of the mountains; and this collects either as a slight efflorescent crust on the surface, or in crystals and in masses throughout the material of the ejected clays, ashes, &c. Speaking of the sulphur mountains of Iceland, Sir George Mackenzie says: 'At the foot of an elevation, in a hollow formed by a bank of clay and sulphur, steam rushed with great force and noise from among the loose fragments of rock. Ascending still higher, we came to a ridge composed entirely of sulphur and clay, joining two summits of the mountain. Here we found a much greater quantity of sulphur than on any other part of the surface we had gone over. It formed a smooth crust, from a quarter of an inch to several inches in thickness: the crust was beautifully crystallised. Immediately beneath it, we found a quantity of loose granular sulphur, which appeared to be collecting and crystallising as it was sublimed along with the steam. Sometimes we met with clay of different colours—white, red, and blue—under the crust; but we could not examine this place to any depth, as the moment the crust was removed, steam came forth, and proved extremely annoying. We found several pieces of wood, which were probably the remains of planks that had been formerly used in collecting the sulphur, small crystals of which partially covered them. There appears to be a constant sublimation of this substance, and were artificial chambers constructed for the reception and condensation of the vapours, much of it might probably be collected.' Such is the usual origin of native sulphur—a substance of greater commercial value to a country like Britain than the most of our readers may imagine. It is employed for making gunpowder, sulphuric acid—which is indispensable to so many manufacturing processes—cinnabar, and for a variety of other purposes in the arts, as well as being used medicinally—requiring altogether an annual supply little short of 20,000 tons. For a further account of the nature and properties of sulphur, and of the manufacture of sulphuric acid, see CHEMISTRY. Orpiment and realgar, the one a yellow, and the other a red sulphuret of arsenic, though found in a mineral state, and as such used in the arts, will be more systematically treated under METALS AND METALLURGY.

PRECIOUS STONES.

All our so-called 'precious stones'—the diamond, ruby, emerald, amethyst, &c.—are but compounds of carbon, alumina, silica, lime, &c., and might therefore, so far as their mineralogical character is concerned, have been considered under the sections already presented. As none of them, however, occur in rocky masses, but rather as crystals, geodes, and concretions within other rocks, and as fashion has generally set a price upon them wholly disproportioned to their utility, it may be as well to treat them as an independent class. Our limits will only permit us to mention a few of the more esteemed; seeing that lapidaries, jewellers, and others, have vastly increased the nomenclature of precious stones by giving individual names to specimens which are, in reality, but varieties of the same substance. For an account of *pastes*, or *artificial gems*, see FICTILE MANUFACTURES; and for *pearls*, native and artificial, which are often erroneously classed with gems, see ZOOLOGY and FISHERIES.

Diamond.

The most highly prized of precious stones is the diamond, a crystalline mineral of unsurpassed lustre and hardness. It is the hardest known substance, and can be polished or cut only by its own dust or powder; hence the common saying of 'diamond cut diamond.' When perfectly pure, it is as transparent as a drop of the purest water, in which state it is known as a diamond of the first water; and in proportion as it falls short of this perfection, it is said to be of the second, third, or fourth water, till it becomes a coloured one. Coloured diamonds are generally yellow, blue, green, or red, and the higher the colour, the more valuable they are, though still inferior to those absolutely transparent. Diamond, as has been demonstrated by numerous experiments, consists solely of carbon, being, in fact, a crystallised charcoal, generally appearing in one or other of the subjoined forms:



Diamonds were originally discovered in Bengal, but they have since been found in other parts of India, in the East India islands, in the Brazils, and recently in the Ural Mountains. They occur chiefly in alluvial deposits of gravel and sand, lying in detached octohedral crystals, sometimes with plain, but more frequently with rounded surfaces. The finest are cut for ornamental purposes into *brilliants*, having curvilineal faces both at top and bottom; or into *rose diamonds*—that is, those having their tops or upper surfaces cut into a number of triangular facets, but quite flat beneath. The black, dirty, and flawy ones, and those unfit for being cut (technically called *borts*), are pulverised for the purpose of polishing others, besides being applied to various uses in the arts. Fractured portions, with good cutting edges, are usually set for glaziers' cutting-pencils, in which state they are worth from twelve to twenty shillings; and also as *drills* for piercing other precious stones. It is the ornamental diamonds that bring the exorbitant

prises so frequently mentioned in modern history, their value depending upon shape, colour, and purity, and being fixed at so much per carat of 3¼ troy grains. The diamond which we know most about in this country is the Koo-i-noor, which is now the property of Queen Victoria, and was exhibited in the Great Exhibition of 1851. This diamond originally belonged to Runjeet Singh, who usually wore it upon his left arm, according to the custom of Eastern potentates, but who often decorated his horse with this and other diamonds to the value of £300,000, the great Koo-i-noor being placed on the pommel of the saddle. When this diamond was exhibited at the Crystal Palace, it weighed 186$\frac{1}{16}$ carats, but it was immediately thereafter reduced, by cutting, to 102$\frac{13}{16}$ carats. To arrive at an estimate of the value of the Koo-i-noor, it is only requisite to multiply 102 (its weight) by 102, and then by 8, which gives £83,232 as its present value. The largest diamond ever known was brought to the king of Portugal from Brazil. It is uncut, weighs 1680 grains, and its value is often quoted at £5,644,800. Similar extravagant valuations are applied to the famous Russian one weighing 193 carats; to that in the possession of the Great Mogul, weighing, cut, 280 carats; and to others; but it does not appear that any sum exceeding £150,000 has ever been given. The last great sale of jewels was in London in 1837, for the distribution of the Deccan booty, obtained by the army under the Marquis of Hastings. On that occasion, the magnificent Nassau diamond, weighing 357½ grains, of the purest water, brought only £7200. The Russian diamond, says another authority, is of the size of a pigeon's egg, and was purloined from a Brahminical idol by a French soldier; it passed through several hands, and was ultimately purchased by the Empress Catherine for the sum of £90,000, an annuity of £4000, and a title of nobility. Perhaps the most perfect and beautiful diamond hitherto found is a brilliant brought from Malacca by a gentleman of the name of Pitt, who, after getting it cut in London, sold it to the Regent, Duke of Orleans, for the sum of £130,000; its weight 139 carats. It is now, or rather we should say was lately, in the crown-jewels of France; its further history is a problem yet to be solved.

The art of cutting diamonds—which is distinct from that of the lapidary or polisher of inferior gems—is thus described by Webster: The gem may be split by a steel tool if a blow be applied; but to effect this it is necessary to have a perfect knowledge of its crystallised structure; and the workman cannot form facets at pleasure by splitting. To produce the faces which are required for exhibiting the gem in all its beauty, the process called *cutting* is resorted to, but which is, in fact, abrasion rather than cutting. For this purpose, the diamond is fixed on the end of a stick or handle, in a small ball of cement; that part which is to be reduced being left to project. Another diamond is also fixed in a similar manner, and the two stones are rubbed against each other with considerable force, until they are ground away as much as is necessary to produce a facet. Other facets are formed in a similar way by shifting the position of the diamonds in the cement. When the faces are thus completed, they are next to receive an exquisite polish. For this purpose the stones are imbedded in soft solder, contained in a small copper cup, the faces to be polished being left to protrude. A flat circular plate of cast iron is then charged with diamond-powder, and the stone is held against this plate, while it is made to revolve till the polish is complete.

Sapphire—Ruby—Topaz—Garnet, &c.

These may be conveniently grouped together as consisting essentially of crystallised alumina — traces of magnesia, silica, fluoric acid, chromic acid, &c., constituting the specific distinctions. The sapphire is of various colours—the *blue* being generally known among jewellers and lapidaries as the sapphire; the *red*, the Oriental ruby, and, next to the diamond, the most valuable of gems; and the *yellow*, the Oriental topaz. Sapphires are sometimes substituted for diamonds, by exposing them to a strong heat, which destroys their colour, but improves their hardness and transparency; and this kind of fraud would be difficult to detect by any one who was not a good judge of these gems.

Corundum, or adamantine spar, is nearly allied to the sapphire, and, with the exception of the diamond, is the hardest substance known. It is almost a pure crystallised alumina, consisting of more than ninety per cent. of that substance, with a little silica and iron. It is found in India, China, and some parts of Europe; and is used in the East for the same purposes to which diamond-powder is applied in England. Emery, so called from Cape *Emeri*, in the island of Naxos, is but a variety of corundum, with an admixture of iron, which gives to it a bluish-gray colour. From its extreme hardness, its powder is largely employed in the polishing of glass and metals, and in the cutting of gems and other minerals—all of which are abraded by it, with the exception of the diamond. Emery-powder is prepared by grinding the mineral in steel mills; it is afterwards assorted into parcels of different degrees of fineness, by agitating it with water, and separating the particles which deposit themselves at different stages—the finest being the last which subside. Emery-paper and emery-cloth are prepared like common sand-paper—namely, by coating the fabrics with a strong size of glue, gum, flour, and alum, upon which the powder is sifted while the size is sufficiently soft to retain it.

The ruby, found chiefly in the sand of rivers in Ceylon, Pegu, and Mysore, is also of various colours—the scarlet-coloured being distinguished as *spinelle ruby;* the pale or rose-red, *balass ruby;* and the yellowish-red, *rubicelle*. Rubies from two to six carats are rare, and when of this size, and of the fine deep cochineal red so much prized, fall little short of the diamond in value. The topaz likewise presents various shades between yellow and wine-colour; but, from its large percentage of silica, is harder than either of the preceding. The best varieties are known as the Brazilian, the Saxon, Siberian, and Scotch.

The garnet, another well-known mineral, belongs to the same section, the varieties being essentially composed of alumina, with silica, magnesia, iron, &c. The most valuable is the *precious garnet*, almandine, or carbuncle, which is commonly a transparent, red, and beautiful mineral, either crystallised, or in roundish grains. It is found in Ceylon, Pegu, and Greenland. The *pyrope*, a blood-red variety, found in Germany and Ceylon, is perfectly transparent, and, in roundish or angular grains, is perhaps next in value. The common garnet is not transparent like the preceding, and is most frequently of a dull-red or blackish-brown. It is found plentifully in Scotland, Sweden, and other countries, where the primitive rocks abound; but comparatively few specimens are fit for the jeweller. The black garnet, or, more properly, *melanite*, is a mineral found in volcanic rocks, and worked into necklaces at Naples.

Emerald—Beryl—Amethyst—Carnelian, &c.

In these the predominant ingredient is silica; they may be called silicious gems, just as the ruby and sapphire might be styled aluminous, or the diamond carbonaceous. The emerald is one of the most esteemed, being of a beautiful green colour, and occurring in prismatic crystals. It consists essentially of silica, with a small percentage of alumina and glucina, the colouring-matter being oxide of chromium. The finest emeralds are brought from Peru and Brazil; the mines from which the ancients obtained their supply are said to have been in Upper Egypt. Fine emeralds are extremely rare; and one of four carats, of approved hue, and well cut, is worth about £160. Beryl differs little

from emerald except in colour—the latter name embracing the green varieties, the former all those that are tinged less or more with yellow or blue, or are altogether colourless. Beryls are found in Siberia, France, the United States, and in Brazil, the latter country furnishing the brilliant variety known as the precious beryl, or aqua-marine. Heliotrope, or *bloodstone*, is another common deep-green silicious mineral, somewhat translucent, and often variegated with blood-red spots—whence its common appellation. It is found in Siberia, in Iceland, and the Hebrides, but chiefly in India, which furnishes the finest specimens. It is in request among the Chinese as an ornament to their girdle-clasps.

Amethyst is a pure rock-crystal, of a purplish-violet colour, and of great brilliancy. It is found in India, in Germany, Sweden, and Spain, but chiefly in Brazil, and is in great request for cutting into seals, bracelets, and brooches. 'Some of the ancient vases and cups,' says Brande, 'are composed of this mineral, and it was an opinion among the Persians that wine drunk out of such cups would not intoxicate; hence its name from the Greek *amethystos*.' The cairngorm of the lapidary is another crystallised quartz, of various hues, and nearly transparent. It derives its name from the mountain Cairngorm in Inverness-shire, and is much used as an ornamental stone in this country.

Agate, chalcedony, opal, carnelian, sardonyx, jasper, and some kindred substances, may be, without much impropriety, regarded as merely varieties of the same mineral, having different colours and degrees of transparency. They are found in most countries, and are used for seals, brooches, cameos,* and other ornamental purposes—the larger geodes or mass being often fashioned into cups and vases. Carnelians and opals are perhaps the most valuable, some specimens of the Oriental opal being worth double the price of a sapphire of the same size. This variety is sometimes known as the Nonnius opal, from the senator Nonnius, the possessor of the famous opal of Rome, worth 20,000 sesterces, who preferred banishment to parting with it to Antony. The *cat's-eye* opal, so called from its presenting an effulgent pearly light, like the changeable reflections of the eye of a cat, is another silicious mineral or quartz, interspersed with filaments of asbestos. It is found chiefly in Ceylon and the Indian peninsula, and is held in great estimation among gem-fanciers. When the late king of Kandy's jewels were brought to the hammer in London, in 1820, a specimen, which measured about two inches in diameter, brought upwards of £400. *Mocha-stone*, also in some repute, is a semi-transparent chalcedony, enclosing various ramified forms produced by oxide of iron, or other metallic substances, but sometimes also by the presence of vegetable bodies, such as mosses. The finest are found in Gujerat, but receive their name from being brought from Mocha. The *onyx*, so much admired by the ancients, is a species of agate, in which the silicious particles are arranged in alternating horizontal layers of opaque white and translucent blue, gray, or brown. It is employed for cameos, the figure being cut out of the opaque white, and the dark part forming the ground, or *vice versâ*. It is most valuable when the colours are in strong contrast, and when the layer is thick enough to give a high relief to the object engraved.

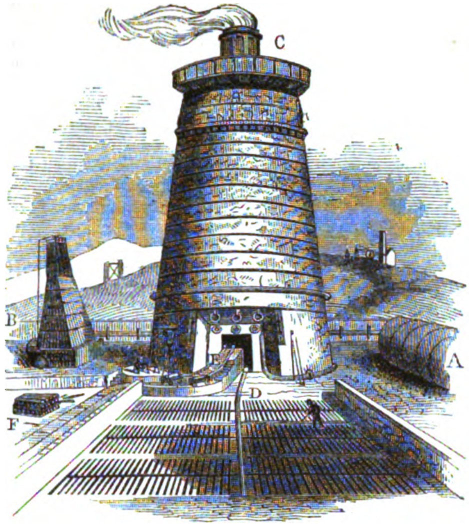
The district of Cambay, in India, yields agates, chalcedonies, carnelians, and jaspers of every variety, and of enormous size; and these, now so common in the market, are known by the general name of *Cambay Stones*. Great numbers of people find constant employment in quarrying these. When first taken from the rock, their colours are faint, and tracings imperfect. They are first exposed for some time to the air, and afterwards heated nearly to redness by a slow fire of wood or cow-dung. Under this process, the colours come out in the greatest brilliancy. They are now cut up by the common lapidaries' wheel, and polished in the usual way with emery or ground corundum. Cutting is but rarely resorted to: in general, the stones are chipped as nearly to the required form as possible, and then ground with emery and polished. They form a considerable article of sale in the Bombay market, and are imported in immense quantities by the London lapidaries, who improve their polish, and alter their forms into such as may be considered most saleable. The Bombay brooch and necklace pieces, paper-folders, finger-rings, shirt-buttons, ear-ring drops, &c., are those most frequently found on sale.

Lapis-lazuli, or azure-stone, at one time held in the highest estimation, is another precious mineral, whose chief constituents are silica and alumina. Its principal localities are China, Persia, and Siberia, where it occurs in massive, but rarely in regular crystals. The finer specimens are prized by the lapidary; but by far the most important application of the substance is to the production of ultramarine—a pigment which, till of late, was more precious than gold. Within these few years, however, the chemist has succeeded in producing an artificial ultramarine, possessing all the properties of the native pigment, and at such a rate that several pounds weight can be procured for what, twenty years ago, would scarcely have purchased a single ounce.

Calcareous Spars.

Several of the calcareous spars are of great beauty and transparency, but in general their softness and frangibility prevent them from being employed for ornamental purposes. *Iceland spar*, so called from the largest and most transparent specimens being found there, is a rhomboidal carbonate of lime, much used for experiments on the double refraction and polarisation of light. *Fluor spar* is a common mineral product, found in many places, but in great beauty and abundance in Derbyshire. It is a fluoride of calcium, occurring in crystals and in nodules of various colours, and often very prettily banded. The nodular specimens are occasionally worked into beads, brooches, and other ornamental purposes; but chiefly manufactured into vases, toilet-boxes, jars, and such-like articles. The acid of fluor spar, when disengaged, is used in etching on glass (FICTILE MANUFACTURES); and the spar itself is occasionally employed, under the blow-pipe, as a flux for promoting the fusion of other minerals.

* *Cameo* (a word of Oriental origin) is the term applied to gems of various colours sculptured in relief. 'The art of engraving on gems,' says Brande, 'boasts of high antiquity, having been practised with various degrees of success by the Egyptians, Greeks, and Romans. It was again revived in Italy in the fifteenth century, and is even at the present day cultivated with great avidity and considerable success. The cameos of the ancients were usually confined to the agate, onyx, and sard, which, on account of the variety of their strata, were better accommodated to a display of the artist's talents; but they are also occasionally found executed on opal, beryl, or emerald, and even on a sort of factitious stone, the *Vitrum obsidianum* of Pliny, distinguished by the moderns as the antique paste. One of the most famous cameos is the onyx at present in Paris, called the *apotheosis of Augustus*. It is one foot in height and ten inches in width.' To this we may add, that a cheap kind of cameo has recently been prepared from large shells found on the coasts of Africa and Brazil. These shells have two layers, the ground being either of a pale coffee colour, or of a reddish orange, and the figure of a nacreous white. Cheap imitation cameos are also extensively manufactured in glass enamel.



Iron-smelting Work.

METALS—METALLURGY.

THE peculiar lustre of the metals—arising out of their opacity and reflective power with regard to light—their conduction of heat and electricity—their density, fusibility, ductility, malleability, and the like, are features which, though differing in each, yet readily distinguish them as a class from all other substances. It is this density and hardness in some, this ductility and malleability in others, and the facility with which many of them can be amalgamated, that have rendered them such valuable aids to human progress, and made them available for almost every purpose of utility or ornament. Without them, indeed, any high degree of civilisation were impossible; they are essential to every process in agriculture, architecture, machinery, navigation—to every art, in fine, which marks the advancement of mankind from the lowest stages of barbarism. As elementary substances, their scientific distinctions have been detailed under CHEMISTRY; we would now direct attention to their history, the localities where found, the modes of obtaining and preparing them, the purposes to which they are applied, their relative values, and other particulars of economic importance.

GEOLOGICAL CONDITIONS.

The metals, as found in nature, are seldom in a state of purity. It is true that the miner occasionally detects a fragment of native metal—pure and ductile as from the crucible of the chemist—but such fragments are rare, and bear no appreciable proportion to the quantity which occurs in the crude state of *ores*. These ores are sulphurets, carbonates, oxides, &c., mingled with earthy impurities, generally situated in veins, sometimes disseminated through rocky masses, rarely in beds or strata, and distributed through the formations of all eras, but more especially through those of the primary and transition series. Thus, iron, the most familiar and useful of all the metals, occurs in more than twenty different mineral states, being combined with carbon, oxygen, sulphur, phosphorus, &c.; is found in veins traversing different formations; is disseminated through various rocks, so as to give to them a ferruginous aspect; and, as clay-ironstone, is interstratified with the clays and shales of the coal-measures. To arrange and classify the ores is the study of the mineralogist; to determine their value, or the amount of metal they contain, is the art of the chemist; to raise them from their various positions, is the labour of the miner; to separate the metal from the earthy impurities with which it is associated, is the work of the metallurgist; and to fashion it into implements, utensils, and machines, is the calling of the founder, blacksmith, machinist, cutler, and others. As with the ores of iron, so with those of the other metals, only that few of them can be said to occur stratified like the clay or carbonaceous ironstone. It must not be supposed, however, that the respective metals always lie in separate veins—that copper, for example, is always the only metal found in a copper vein; or lead in a so-called vein of lead. The fact is, that though some one metal generally predominates, three, four, or even more metals, may be strangely combined and intermixed in the same veinstone. In our own island, the vein which contains lead as the principal metal, often embodies silver, zinc, and cobalt: platinum is generally associated with gold; manganese not unfrequently with iron.

Beds—Veins.

The natural position in which the metalliferous ores generally occur is *veins*, *beds* or *strata*, and *fragmentary deposits*. In the last of these, the ore is associated with sand, gravel, and other superficial débris, which have evidently been transported by alluvial agency from mountain metalliferous districts. The *strata* are for the most part composed of earthy matter, less or more impregnated with one or other of the metals, but it is only those in which the metallic ingredient is peculiarly abundant that demand the attention of the miner. *Veins*, however, are the principal forms in which

metallic ores are distributed throughout the crust of the globe.

A vein may be said to resemble a deep cleft or rent in a clayey field, which has been subjected for some time to the desiccating influences of the sun. This cleft, whatever may be its depth, must of course have a direction underground, either slanting or perpendicular; and if we suppose it filled with metallic ore, we form the idea of a vein, or, as it is termed, a *lode:* if we suppose the cleft filled with a stony substance, we can imagine what is called a non-metalliferous vein or *dike*, of which there are many, sometimes pursuing their own exclusive courses, and at other times intersecting the metalliferous veins. The direction of the lodes is by no means accidental, but nearly determinate. They usually *strike* east and west, and *dip* or underlie either towards the north or south; while the non-metalliferous veins, which run north and south, dip either towards the east or west. The cases in which metalliferous veins assume a north and south direction are few, and chiefly foreign. It frequently happens that the metalliferous lodes, as we have said, cross each other; and, as a leading fact, the intersection of two lodes at a small angle is productive of good ore.

The compositions of the lodes or veins are as variable as the nature of the rocks through which they pass. By far the greater number consist of matter similar to that of the contiguous or intersected rock; but many also contain large intermixtures of quartz. These ingredients for the most part are mingled without regularity or order, and throughout them are dispersed the metallic ores. Sometimes these are aggregated very thickly, and very generally occur in large irregular lumps or patches, called *bunches*, connected with each other by small films or *threads* of ore. On referring to the *known* depths to which different metals extend, it will be found that those which commonly lie near the surface, as lead, zinc, gold, and occasionally tin, do not generally penetrate to any great depth; while those which lie deeper, as copper and silver, are worked in the bottoms of our deepest mines. This arrangement may be the result of a natural law, or it may be apparent, and consequent only upon the limit of our experience and knowledge.

MINING OPERATIONS.

A mine in a complete working condition exhibits a most extensive series of operations, in connection with the shaft, the lifting and descending by ropes and pulleys, the drainage, the excavation, the ventilation, &c. (fig. 1). At the bottom of the shaft, and in the various stages in which the excavations are going on by the miners, in their attempts to follow the lodes, the operations are on a scale which seldom fails to surprise the stranger. When the levels have been carried to a considerable distance from the shaft, the ventilation will be found defective. This deficiency is still further augmented by the increasing number of the men now employed in the works, the presence of a great number of candles and lamps, and the smoke resulting from the larger employment of gunpowder in the process of blasting. The irregular distribution of the metalliferous portions of the lode becomes the cause of inequality in the workings, and renders the sinking of one or more shafts indispensable.

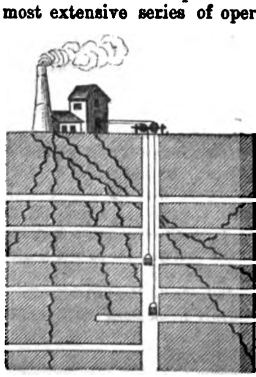


Fig. 1.

When circumstances permit, mines are entered by an adit in a hillside, instead of by shafts. Of this character are the openings into the lead-mines of the north of England, of Derbyshire, and of North Wales, all of which are situated in the carboniferous limestone, and the grits and shales resting upon it. Where the edges of the strata are exposed to view, a spot is selected from which it may be practicable to drive a level upon the vein itself, and in one of the beds known to be favourable to its productiveness. The mining of stratified ores, as the clay or carbonaceous ironstone, is conducted precisely in the same manner as coal.

METALLURGY.

Metallurgy—from the Greek *metallon*, and *ergon*, a work—is the art of separating metals from their ores; and as this separation is undertaken only with a view to some economic purpose, the term may be regarded as embracing the whole art of working in metals, from the reduction of the ore, to the ultimate application of the metallic product. With respect to the primary reduction, though heat be the grand agent, yet so different is the treatment of the different ores as to dressing, roasting, smelting with fluxes, the application of amalgams, and the use of even more complicated chemical processes, that what is peculiar in each, will be best adverted to under our notices of the respective metals, which are here tabulated with their specific gravities, taken at 60° Fahrenheit:

Name.	Specific Gravity.	Melting-Point.	Discoverer.	Date.
Platinum,	21·5	ox. bl.*	Wood,	1741

Gold.

As the most valuable and longest known of the metals, gold deserves to rank first in our catalogue. When pure, it is of a deep and peculiar yellow colour, rather soft, and extremely heavy, having a specific

* Ox. bl.—Fusible only before the oxy-hydrogen blow-pipe.

gravity of 19·5—that is, nineteen times heavier, bulk for bulk, than pure water. It exceeds all the other metals in ductility and malleability: it may be beaten into leaves 1-282,000th of an inch in thickness, and a single grain may be drawn out into 500 feet of wire. Though soft, its fusing-point is as high as 2016° of Fahrenheit; it is unchanged by fire with access of air—the hottest furnace producing no other effect upon it than to keep it in fusion. It expands during fusion, and contracts in cooling, more than any other metal. It is not acted upon by any of the common acids; but chlorine and a mixture of hydrochloric and nitric acids (*aqua regia*) corrode and dissolve it, forming a chloride of gold, which is soluble in water. The metal occurs in greater or less abundance in almost every quarter of the globe, and is obtained either in the native state, from alluvial sands and gravels, or in mineral veins in combination with silver, and often mixed with metallic sulphurets and arseniurets. In the native state, it occurs in small crystals, in threads or granular fragments, which, when of a certain magnitude, are called by the name of *nuggets*.

The geological formations in which gold occurs are the crystalline primitive rocks, the compact transition strata, the trachytic and trap rocks, and alluvial grounds of the current era. In the three former sources, the ores of the metal are *in situ;* in the latter, it is a travelled or transported product, being carried thither, from the rocks in which it was originally formed, by streams and rivers. In the former case, it is obtained by the difficult and dangerous process of mining; in the latter, the soil or gravel is merely turned over, and the metallic portions—the *gold-dust* of commerce—separated by hand-picking, washings, and siftings. It is thus obtained from *mines* in Brazil, Peru, Mexico, Hungary, Transylvania, and the Uralian Mountains; and from *sands* from the Peruvian, Mexican, and Brazilian rivers, the coast of California, several of the rivers of Africa, from the Rhine, Rhone, and Danube, in continental Europe, and in small quantities from Wicklow in Ireland, from Cornwall, and from the Leadhill district in Scotland. The great sources of gold at the present day (1857) are the alluvial plains of California and Australia. The latter country seems to possess an inexhaustible supply of this precious metal. With the exception of iron, perhaps there is no metal more generally disseminated than gold; but in comparatively few localities is it sufficiently abundant to repay the cost of mining and collecting. The deposits, for example, in our own country are quite insignificant; that of Wicklow, to be sure, yielded some years ago a few thousand ounces, but is now, we believe, abandoned like all the other localities.

The following is the treatment of the gold ore as practised at one of the most extensive mines in Brazil: The ore is first removed from its bed by blasting, and is afterwards broken by female slaves into small pieces, about the size of the stones put upon macadamised roads; after which it is conveyed to the stamping-machine, to be reduced to powder. This machine consists of a number of perpendicular shafts placed in a row, and heavily loaded below with large blocks of iron; these, being alternately lifted up to a certain height by a toothed cylinder, turned by a large water-wheel, fall down upon and crush the stones to powder. A small stream of water, constantly made to run through them, carries away the pulverised matter to what is called the *strakes*, a wooden platform, slightly inclined, and divided into a number of very shallow compartments, of fourteen inches in width, the length being about twenty-six feet. The floor of each of these compartments is covered with pieces of tanned hide, about three feet long and sixteen inches wide, which have the hair on; the particles of gold are deposited among the hairs, while the earthy matter, being lighter, is washed away. The greater part of the gold-dust is collected on the three upper skins, which are changed every four hours; while the lower skins are changed every six or eight hours, according to the richness of the ore. The sand which is washed from the head skins is collected and amalgamated with quicksilver in barrels; while that from the lower skins is conveyed to the washing-house, and concentrated over strakes of similar construction to those of the stamping-mill, till it be rich enough to be amalgamated with that from the head skins. The barrels into which this rich sand is put, together with the quicksilver, are turned by water, and the process of amalgamation is generally completed in the course of forty-eight hours. When taken out, the amalgam is separated from the earthy sand by washing; it is then pressed in chamois skins, and the quicksilver is separated from the gold by sublimation. In different countries, various metallurgic processes are adopted; but, on the whole, that of stamping and amalgamating seems to be the readiest and most successful. The metallic grains found in the sands of rivers do not require to be subjected to any metallurgic process, in the strict acceptation of that term.

The applications of gold are numerous and important; but in most cases it is used in an alloyed, and not in a pure state. This arises from its softness, and consequent liability to be worn down; the common alloys of copper or silver conferring the necessary hardness, without impairing in any appreciable degree the beauty and lustre of the more precious metal. In this condition it is employed for coin, plate, and a variety of articles of luxury and ornament, for which purposes it has ever been in the highest repute. It is also extensively used in the arts for gilding, conferring on materials often the most worthless the semblance of its own unrivalled beauty. The gold coin of the realm, commonly called *standard gold*, consists of 11 parts pure gold and 1 of copper; it is extremely ductile and malleable, but harder than pure gold, and therefore better calculated to resist the wear and tear of circulation. The colour of this alloy is deeper yellow than that of pure gold, and verges upon orange; 20 pounds troy of it are coined into $934\frac{1}{2}$ sovereigns; 1 pound troy, therefore, produces $46\frac{29}{40}$ sovereigns. It sometimes happens that a part of the alloy of gold coin is silver; hence the pale colour of some sovereigns as compared with others. The gold employed by jewellers, &c., is all less or more alloyed; and from the great skill now attained in putting rich surfaces on such alloys, it requires very considerable skill on the part of the purchaser to prevent deception. The art of *gilding* consists in covering other substances with a thin coat of gold, which may be done either by mechanical or chemical means. The mechanical mode is the application of gold-leaf or gold-powder, which is made to adhere by size or varnish; the chemical, by plunging the substances in solutions of gold, or by the electrotype process. The production of *gold-leaf* and *gold-wire* of such extreme fineness as we have mentioned, requires considerable ingenuity; and is all the more readily accomplished the finer the standard of the metal. The former is made by rolling out plates of pure gold as thin as possible, and then beating them between folds of fine vellum—gold-beaters' skin—by a heavy hammer, until the requisite degree of tenuity has been reached; the latter is formed by drawing a cylindrical rod of the pure metal through a series of gradually decreasing holes punched in a steel plate.

Silver.

This is another of the metals which have been longest known and esteemed, having been extensively employed from the earliest times in the fabrication of articles both of utility and ornament. Every one must be familiar with its peculiar white colour and great lustre; the epithet *silvery* conveying an idea not to be confounded with any other. In malleability and ductility, it ranks next to gold, being frequently hammered into

leaves 1-10,000th part of an inch in thickness, and drawn into wires finer than the human hair. Its specific gravity is only 10·5, and its fusing-point 1873° of Fahrenheit. Silver is a widely disseminated product of nature, occurring in the metallic or *native* state in fine threads or strings in various rocks, but chiefly in veins in primitive and secondary mountains. It is found also in combination with other metallic ores, as those of lead, and as a native sulphuret.

Silver, we have said, is very generally distributed; but the great sources of supply are Mexico and Peru in the New World. A considerable supply is also obtained from other parts of South America, from the Uralian Mountains, Austria, and Norway. In Britain, it is found in small quantities, associated with lead—as in Derbyshire, at Alston Moor, Leadhills, &c.; and also in veins in the island of Anglesey. Most of the silver-mines are situated in high, bleak, desolate tracts, which would never be inhabited by man, unless for the sake of the treasures in the rocks beneath. Those of Peru, for example, are found at an elevation of from 12,000 to 14,000 feet above the sea, in a wild barren region, to which every necessary of life has to be brought from a toilsome and expensive distance; and yet towns like Cerro de Pasco, of 18,000 inhabitants, have there risen into life and activity. The silver veins of Pasco are extremely rich. One of them has already been traced to the length of 9600 feet, and the breadth of 412 feet; another is known to the extent of 6400 feet long, and 380 feet in breadth. From these large veins, numberless smaller ones branch off in various directions, so that a net-work of silver may be supposed to spread beneath the surface of the earth. Some thousand openings, or *mouths*, are the entrances to these mines. Most of these entrances are within the city itself, in small houses; and some are in the dwellings of the mine-owners. All are worked in a very disorderly and careless way, the grand object of their owners being to avoid expense. All the other operations, it would appear, are as rude as the mining: the raising of the ore, the breaking and stamping, the separating of the silver from the dross, are all executed in a very clumsy, imperfect, and at the same time a very expensive manner. 'The amalgamation of the quicksilver with the metal is effected by the tramping of horses! The animals employed in this way are a small ill-looking race, brought from Ayacucho and Cuzco, where they are found in numerous herds. The quicksilver speedily has a fatal effect on their hoofs, and after a few years the animals become unfit for work. The separation of the metals is managed with as little judgment as the amalgamation, and the waste of quicksilver is enormous. It is computed that on each mark of silver, half a pound of quicksilver is expended. The quicksilver, with the exception of some little brought from Idria and Huancavelica, comes from Spain in iron jars, each containing about seventy-five pounds' weight of metal. In Lima, the price of these jars is from 60 to 100 dollars each, but they are occasionally sold as high as 135 or 140 dollars.

The numerous uses and applications of silver are well known. In its pure state, it is too soft for coin, plate, and most ornamental purposes; but alloyed with copper in proper proportions, it becomes hard, without being materially impaired in colour. The *standard silver* of British coin is an alloy of 11 ounces 2 pennyweights of pure silver, and 18 pennyweights of copper, to the pound troy; and this weight is coined into sixty-six shillings. In the arts, silver is extensively used, particularly for silvering or plating other metals; and for this purpose, silver-leaf and solutions of silver are applied much in the same way as in gilding. The oxide of silver is used for colouring porcelain; and several of its salts are now largely employed as the principal agent in preparing photographic portraits. The only pure acids which dissolve silver are the nitric and sulphuric, producing respectively nitrate and sulphate of silver. The nitrate, for example, is the strongest and most manageable caustic known in surgery, being applied as a common black wash, or as *lunar caustic*, which is merely the nitrate melted and run into moulds after evaporation. A solution of two drachms of the nitrate of silver in an ounce of water, coloured by a little sap green or Indian ink, forms the marking-ink of the laundress; and when a solution of nitrate of silver is mixed with alcohol, a violent effervescence ensues, and *fulminating powder* is produced. This powder is one of the most dangerous compounds known, exploding with violence upon the slightest friction, or when struck, rubbed, or heated.

Copper.

This was one of the earliest known of the metals, and not less extensively used than known by the nations of antiquity; its tenacity and durability rendering it the best substitute for iron, ere man had learned to reduce that valuable but more refractory metal. It derives its name from the island of Cyprus, where it was extensively mined and smelted by the Greeks, who employed it either pure, or in an alloyed state (bronze), in the fabrication of their domestic utensils and implements of war. It is a metal of a beautiful red colour, and considerable lustre, very malleable and ductile, but more capable of being hammered into leaves than drawn into wire. In tenacity, it yields to iron, but surpasses gold, silver, and platinum—a wire of only $\frac{1}{10}$th of an inch being strong enough to support a weight of 300 pounds. Its specific gravity is 8·96, and its fusing-point, 1996° Fahrenheit—that is, nearly a white heat. It is found occasionally in a native state in films, strings, or amorphous masses, but in no considerable quantity. The most remarkable masses of native copper hitherto discovered are said to be one in Brazil, which weighed about 2620 pounds; another in the bed of a stream to the south of Lake Superior, which measured not less than fifteen feet in circumference; and a third in Australia, which was exhibited at a festal inauguration of a mining company in Adelaide. The great source of the commercial supply is, as in the case of the other metals, from ores, of which the most productive is copper pyrites—that is, copper in certain combinations with sulphur and other metallic impurities. In this state it is found in almost every mineral district in beds—as the *kupfer-schiefer*, or copper-slate, of Germany—but more commonly in veins in primitive and secondary mountains. A less abundant ore of copper is the carbonate of copper, which often occurs associated with the copper pyrites. Copper-mines are largely worked in England, Chile, Cuba, Germany, Sweden, and Siberia; less extensively in France, Spain, Hungary, and Norway; and recently, with great success, and still greater promise, on the shores of Lake Superior, and in Australia.

The English mines are chiefly situated in Cornwall, where the most common ore consists of copper, iron, and sulphur, in nearly equal proportions, and is called yellow copper ore, or copper pyrites; veins are also worked in the counties of Devon, Anglesey, and Stafford. Owing to the want of fuel in Cornwall and Devon, the ores, after being dressed—that is, ground and sifted—are shipped from these counties to South Wales, to be calcined and smelted, principally to works situated on the navigable rivers of Swansea and Neath; the smaller quantity of material being thus carried to the greater, while the vessels load back with coal for the use of the mining steam-engines. The reduction of the ore is a tedious and complex process. 'It is first roasted in a reverberatory furnace (fig. 2), by

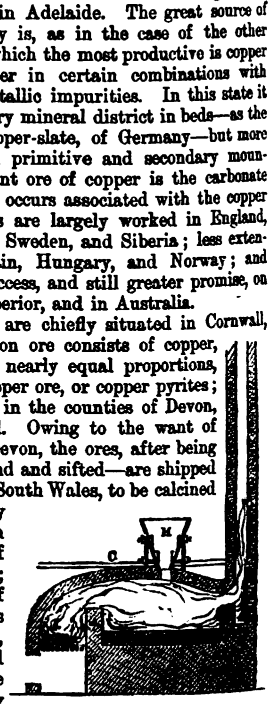

Fig. 2.

which much of the sulphuret of iron is converted into oxide, while the sulphuret of copper remains unaltered. The product of this operation is then strongly heated with silicious sand; the latter combines with the oxide of iron to a fusible *slag*, and separates from the heavier copper compound. When the iron has, by a repetition of these processes, been got rid of, the sulphuret of copper begins to decompose in the flame-furnace, losing its sulphur, and absorbing oxygen; the temperature is then raised sufficiently to reduce the oxide thus produced by the aid of carbonaceous matter. The last part of the operation consists in thrusting into the melted metal a pole of birch-wood, the object of which is probably to reduce a little remaining oxide by the combustible gases thus generated.' The quantity of copper yielded by the ore is commonly about eight or nine per cent.; and the fuel consumed ranges from fifteen to eighteen parts for every part of metal produced.

The quantity of copper mined in Britain in 1820 amounted to 8127 tons; now it is considerably more than double that quantity, and valued at little short of £2,000,000. This supply is more than sufficient for the demand of the United Kingdom; hence considerable shipments in pigs, sheets, nails, wires, &c., are made to the East Indies, China, United States, West Indies, Brazil, Canada, and Holland. Besides the produce of British mines, considerable quantities of ore have of late been imported from Chile, Cuba, and especially from Australia.

The uses of copper are numerous and highly important, the metal ranking next to iron in real commercial value. It is used, as is well known, for coin, for sheeting or sheathing the bottoms of vessels, for boilers, and a great variety of implements and utensils; in the manufacture of blue and green colours; and in medicine. Alloyed with zinc, it forms *brass* and *pinchbeck*—the former containing from 28 to 34 per cent. of zinc. In the formation of brass, the zinc may either be added directly to the melted copper, or granulated copper may be heated with calamine and charcoal-powder. *Gun-metal*, a strong and valuable alloy, consists of 90 parts copper and 10 of tin; *bell* and *speculum metal* contain a much larger proportion of tin, and are consequently brittle and less durable. A good *bronze* for statues is made of 91 parts copper, 2 parts tin, 6 parts zinc, and 1 part lead. The bronze of the ancients was an alloy of copper and tin; and the *argentane* or German silver of the moderns is a compound of copper, tin, and nickel. *Ormolu* is the name given to a particular alloy of 52 parts zinc and 48 copper; and the *Biddery-ware* of India—so called from a town of that name—is a compound of copper, lead, tin, and zinc, rendered black by immersion in a solution of sal-ammoniac, saltpetre, common salt, and blue vitriol. All these alloys are of infinite use, entering into the fabrication of almost every species of machinery, implement, utensil, and ornament—from the drawing, pointing, and heading of a pin, or the stamping of a button, to the casting of a statue, or the founding of a ponderous field-piece. Though thus vieing with iron in its applicability to the purposes of civilised life, its salts and solutions are highly poisonous; hence the frequent evils arising from the use of neglected or ill-cleaned culinary utensils of copper. Water containing copper in solution is changed into a bright blue by the addition of a little hartshorn or liquid ammonia; and into a ruddy brown on the addition of yellow prussiate of potash. On immersing a piece of polished steel in any liquid containing copper, the surface will soon become coated with a film of the latter metal.

What is called *bronzing* is a method of colouring wood, iron, plaster of Paris, or other material, so as to imitate bronze, but which has, in reality, little connection with that alloy. The process is thus indicated in Webster's *Cyclopædia*: 'First, the article is to be painted of a dark colour, such as bronze acquires when it has been very long exposed to the air, or when buried underground. This colour is produced by grinding a mixture of Prussian blue, verditer—a precipitate of oxide of copper with lime—and spruce ochre in oil. What is called *bronze-powder*, sold in the shops, is now to be applied, just before the oil-paint is quite dry, to the prominent parts, where the metal is supposed to have acquired some lustre by being rubbed against. The bronze-powder may be laid on by a ball of cotton-wool, or in a similar manner.' Bronzing thus effected is now much in request; it has the advantage of wearing well, keeping clean, and giving effect to other colours. *Lacquering* is a somewhat allied process, and consists in applying a peculiar varnish either to brass-work, to prevent its tarnishing, or to give tin and articles covered with silver-leaf the appearance of brass. The ingredients of such a varnish are wholly non-metallic, consisting chiefly of turmeric, anotta, saffron, gum-lac, amber, and the like, dissolved in alcohol.

Iron.

This truly precious metal is capable of being cast into moulds of any form; of being drawn out into wires of any desired strength or fineness; of being extended into plates or sheets; of being bent in every direction; of being sharpened, hardened, and softened at pleasure. Iron accommodates itself to all our wants, our desires, and even caprices; it is equally serviceable in the arts, the sciences, agriculture, and war. The same ore furnishes the sword, the ploughshare, the scythe, the pruning-hook, the needle, the graver, the spring of a watch or of a carriage, the chisel, the chain, the anchor, the compass, the cannon, and the bomb. It is a medicine of much virtue, and the only metal friendly to the human frame. The ores of iron are scattered over the crust of the globe with a beneficent profusion, proportioned to the utility of the metal; they are found under every latitude and zone, and in every geological formation.

The forms in which the metal is commonly found in the arts are *crude* or *cast iron; malleable* or *wrought iron;* and *steel.* Neither of these commercial varieties is pure, as they contain more or less carbon, silicium, sulphur, and phosphorus.

The preparation of pure iron takes place only in the chemical laboratory. One method is to introduce into a Hessian crucible four parts of fine iron-wire clippings, and one part black oxide of iron; cover these with powdered hard white glass—a mixture of white sand, lime, and carbonate of potash—and raise to a bright white heat. The oxygen present in the oxide of iron burns away the carbon, &c., in the iron of the wire, and on cooling, a button of pure metallic iron is found in the bottom of the crucible. Another process is to place some red oxide of iron in a porcelain or hard glass tube, raise to a low red heat, and pass a stream of hydrogen through the tube. The hydrogen abstracts the oxygen from the peroxide of iron, forming with it water-vapour, which is carried out of the tube by the rush of gas, whilst pure iron remains behind as a grayish-black powder. In this latter condition, the metal is used in medicine. The former process yields the metal in mass, in which form its properties can be best studied.

Pure iron has a bluish-gray colour, and strong metallic lustre, which is heightened by polishing. It has a specific gravity of 7·84, and is one of the most infusible of metals, requiring the highest heat of a smith's forge to liquefy it. When beaten out under the hammer, it exhibits a granular structure; but when passed repeatedly between rollers, it assumes a fibrous texture in the direction of the length. This fibrous character is best seen in ordinary malleable or bar iron, which is almost pure; and the great difference in the comparative strength of *bar* over *cast* iron depends on this property. The axles of railway carriages are most carefully prepared from iron which has been rolled and re-rolled till the fibrous appearance is

at a maximum; but, unfortunately, such precautions are unavailing, as true fibrous iron, after much wear and tear, especially when repeatedly strained or jolted, gradually loses its thread-like structure, and becomes crystalline and brittle. This alteration in the arrangement of the physical atoms of the iron of axles, doubtless occasions many serious accidents on our railways.

When raised to a red heat, iron admits of being hammered into any form; and subjected to a white heat, two pieces of this metal may be readily and completely joined together. This operation is called *welding*, and no metal can surpass iron in its readiness of being manipulated in this manner. It is powerfully attracted by the magnet, and at the same time becomes magnetic; but it loses this property the moment the magnet is withdrawn. Steel, however, may be rendered permanently magnetic by being rubbed over with a magnet. When exposed to air and moisture, iron absorbs oxygen, and passes into *peroxide* or *red oxide of iron*, in other words, *rust*.

Metallic iron is seldom found native. In Connecticut, a vein of iron was found two inches thick, and capable of being wrought into nails by the blacksmith. In Germany and France, smaller pieces have been found; and very thin plates or scales are disseminated through rocks of the basalt, gneiss, and mica-schist character.

Meteoric iron is more abundant: large masses of ignited matter have been observed to fall from the atmosphere on the earth's surface, and other metallic masses have been found in situations which leave no doubt of their having been placed there under similar circumstances. In 1803, a shower of meteoric stones, about 3000 in number, fell at L'Aigle, in Normandy, some of which weighed seventeen pounds each; and other masses have been observed to fall, or have been found, at Braunau in Bohemia, at Harmony Creek in North Carolina, at Atacama in South America, in Brazil, and in Siberia. These meteoric masses are of two kinds: at times they consist mainly of metallic iron in a massive condition, but perforated with many holes filled with stony matter, which gives the metallic portion a branched appearance; whilst occasionally they are essentially of a rocky consistence, in which the iron is imbedded in grains or small pieces. Meteoric iron is good to work, and it is probable the original Damascus blades were made from this material. The Emperor Alexander I. of Russia had a sword made from such iron, which was so pliable that it could almost be bent in two; and the Esquimaux were found in possession of knives, &c., which had been fabricated therefrom. The swords of the caliphs, as related by the Arabian poets, were forged from meteoric or *heaven-descended* iron, and are described as 'glancing like a lightning flash, cutting through marrow and bone; he who wields it has all before him; steel and precious stones vanish like water before its brilliancy.'

Though rarely found as a metal, iron is abundantly and widely distributed in other conditions. All spring and river waters contain more or less iron in solution, and in some the quantity is so great, that an ochrey deposit takes place on the stones over which the water flows, or in the lakes into which the ochrey springs enter. All soils contain iron, to which they owe their red or rusty aspect, and the majority of stones are composed in part of this metal. A compound of sulphur and iron, called iron pyrites, occurs in roofing-slates and elsewhere; but the quantity of iron so distributed, though considerable, is not available for the manufacture of the metal, as the sulphur associated with it renders it objectionable.

The main sources of iron in this country are the *red-iron ore* or *hæmatite*, and the *black-band ironstone*. The former is found largely in Cornwall and Cumberland, and constitutes the principal English ore. It is generally obtained in a compact state, often fibrous in structure, and sometimes presents, externally, a nodular, kidney, or reniform appearance. When mixed with clay, it constitutes *red ochre*. The black-band ironstone is the ore generally worked in Scotland. It occurs in great abundance in a broad belt which stretches across Scotland, the central line and direction of which is represented by the firths of Forth and Clyde. It is found in layers or strata, some distance below the surface of the ground, and interlayered with coal and limestone. On the continent, in Norway, Sweden, &c., as likewise in Elba and the United States, a third ore of iron is found—namely, the *magnetic-iron ore* or *loadstone*. In this condition, iron is found in such quantity, that it forms small hills, which are powerfully magnetic.

In the manufacture of iron from the black-band ironstone, the first operation is that of roasting the ore. This consists in throwing the blocks of ironstone, as they are brought up the pit-shaft, out on an adjoining field, and setting fire to them. Generally, the ironstone contains so much coaly matter, that when once ignited, it continues to burn of itself. The combustion must proceed slowly; and accordingly it is customary to cover the burning mass with clay or rubbish, to serve as a damper in excluding much air. Were the burning allowed to go on quickly, and the temperature of the mass thus rise high, an iron glass would be formed, from which the after separation of the iron is extremely difficult. Generally, the size of the ironstone hill is such, and the combustion allowed to proceed so slowly, that six weeks are occupied in the burning process, and other six weeks elapse before the red-hot mass has sufficiently cooled down to admit of the workmen pulling it to pieces. The object in roasting the black-band ironstone is to get rid of useless and deleterious matters. The original ore is considered a rich one if it contain one-third of its weight of metallic iron, and the remaining two-thirds of other matters. The true composition of such ores will be best observed from the following

Analyses of Black-band Ironstones.

	I.	II.
Carbonate of iron,	83·52	62·06
Organic (coaly) matter,	13·59	16·23
Carbonate of lime,	0·58	15·36
Carbonate of magnesia,	0·04	0·68
Alumina,	0·31	0·07
Sulphur,	traces.	
Silica,	1·96	5·60
	100·00	100·00
100 parts of the above ironstones contain of metallic iron	40·32	29·93
100 parts of the above ironstones will yield of roasted ore	59·89	59·39
100 parts of the roasted ore will afford of metallic iron	67·32	54·29

The roasting of the ore very much simplifies matters, as what is left as roasted ore consists mainly of iron, oxygen, and a little sand. The same ingredients constitute the red-iron ore or hæmatite; so that in describing the after-parts of the process for the extraction of iron from its ores, the chemical changes referred to as undergone by the roasted iron ore of Scotland, are exactly similar to those which take place during the working-up of the red-iron ore of England.

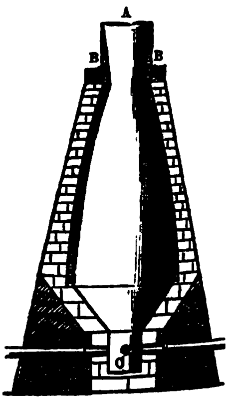

Fig. 3.

The process of extracting the iron from the roasted ore is conducted in a blast-furnace (fig. 3). In external form, it somewhat resembles a sugar-loaf, with

the apex knocked off. Great care must be taken in the construction of the furnace, which is lined with fire-brick in the interior. At the upper part, A, there is an opening for the escape of gases, near which, B, are side-doors, for the introduction of the ore, fuel, &c. At the lower part, there is the crucible, C, as also the pipes or *tuyères*, *b*, *b*, for the passage of air into the furnace. The materials introduced into the furnace are coal, roasted ore, and lime. The coal must be as free from sulphur as possible, and the lime should contain a mere trace of silica, sulphur, and phosphorus. The proportions of coal, iron ore, and lime vary according to their several degrees of purity; but the average amount of each may be observed from the following table, taken from the working journal of a large ironwork:

	Cwt.	Qrs.	Lbs.
Coal,	8	0	0
Roasted ore,	6	2	0
Red ore,	0	2	0
Lime,	2	2	14

The above quantities are thrown into the furnace as nearly as possible at the same time, and constitute one charge. The coal is placed on one wagon, and the ore (*burden*) and lime on a second; and both being raised to the top of the furnace, have their contents discharged therein (fig. 4). The number of such charges thrown

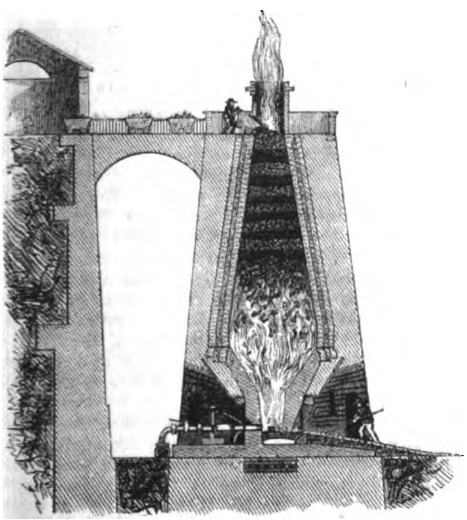

Fig. 4.

into the furnace every twelve hours is about sixty. The feeding-time is from six o'clock in the morning till six at night, and 6 P.M. till 6 A.M. Now, to understand aright the chemical changes undergone by the materials introduced into the furnace, it must be remembered that the iron ore consists of iron, oxygen, and sand, and that the great object of the iron-smelter is to separate the two latter substances from the former. The coal introduced has two functions to fulfil: in part it is burned so as to raise the contents of the furnace to that high temperature that they will be enabled to act on each other; and in other part, it carries away the oxygen which was originally in combination with the iron in the roasted ore. The lime plays the part of a flux, and combines with the sandy matter to form a slag. During the whole operation, hot air is being constantly forced in at the lower part of the furnace, so as to aid in the necessary combustion. The roasted iron ore being thus deprived of its oxygen by the coal, and its sand by the lime, allows the other constituent, the iron, to trickle down through the mass of red-hot cinders to the lower part or hearth of the furnace. The slag produced by the combination of the sand and the lime likewise runs down to the hearth, and there floats on the surface of the molten iron. At intervals, the furnace is worked at the lower part by the introduction of long iron rods, which are moved from side to side; and the slag as it accumulates is allowed to run off. Previous to the *tapping* of the furnace, an arrangement is made to receive the molten iron. Immediately in front of the furnace, a quantity of damp sand is laid, in which a number of little canals or gutters are formed. The larger gutters, called the *sows*, have smaller ones branching off from them, which are termed the *pigs*. At six A.M., or six P.M., everything being in readiness, the blast of air is shut off, the furnace tapped by driving an iron rod through the stopper of hardened clay; and the molten iron runs first into the main sow, then into the lateral sows, and from these into the pigs. When the iron ceases to flow from the furnace, the opening is plugged up by a new stopper of damp clay, the blast set on, and the operation goes on again for the next twelve hours. The working-parts of an iron-smelting work consist, therefore (see Frontispiece), of A, *the receiver*, an arrangement for retaining the compressed air; B, *the heaters*, consisting of an oven, through which the *cold blast* is sent to make it the *hot blast;* C, the smelting-furnace, into which the roasted ore, coal, and lime are thrown, and where the iron is separated from the other ingredients; D, a series of gutters to receive the molten iron; E, an inclined plane to run off the slag; and F, adjoining ground for piling up and storing the bars of iron (*pigs*).

The constituents of pig or cast iron are 95 to 97 per cent. of pure iron, 3 to 5 per cent. of carbon, with minute quantities of sulphur, phosphorus, and silicon. In commerce, the pig-iron is rated No. 1, 2, 3, and 4, according to the quantity of carbon present. No. 1 pig-iron contains most carbon, and is more fusible than the others, hence it is generally preferred for castings, and commands the highest price. No. 4 contains least carbon, is much less fusible, and is principally employed by the worker in malleable iron. Nos. 1 and 2 are often styled *gray iron*, and Nos. 3 and 4, *white iron*. A good workman, who is accustomed to see the white hot metal run off from the blast-furnace, at once knows what quality of iron he will obtain when the molten mass cools.

The iron blast-furnace will be best understood if it is likened to the stomach of an animal. Both are the receptacles of heterogeneous substances, and each in its own way separates the good material from the bad. Both are liable to derangement. If much sand is present in the iron ore or the lime, this serves as the counterpart of bad food, and the furnace suffers from indigestion; and when once wrong, it is difficult to get right again, without the administration of physic, which in the case of the blast-furnace is a liberal dose of good lime.

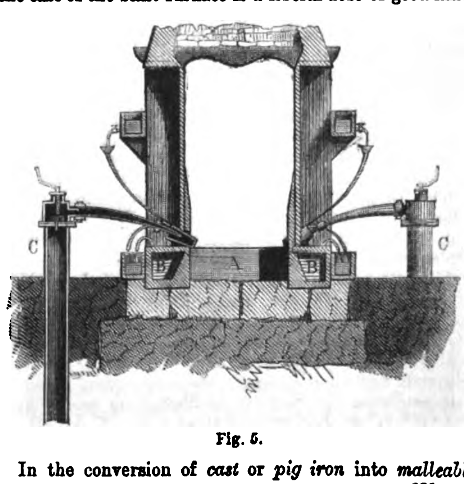

Fig. 5.

In the conversion of *cast* or *pig iron* into *malleable*

or *bar iron*, endeavours are made to retain all the iron, and to get rid of the other substances. This is accomplished by several operations. The pig-iron is first introduced into the *finery* furnace (fig. 5), on the hearth of which, A, much fuel is burning. The lower part of this furnace consists of plates of iron riveted together, and covered with loam or clay in the interior. To keep the sides of the furnace from becoming overheated, a stream of water, B, is constantly circulating round the iron plates; and to aid the rapid combustion of the fuel, hot air is driven in under great pressure from six jets or tuyères, C, C, ranged at the sides of the furnace. When the heat is great, the iron melts, some of its impurities are driven away, and the half-purified iron is run into a shallow trough, where it cools, and solidifies into a plate of *fine metal*, about two inches in thickness. After having undergone the *refinery* operation, the iron is introduced into a *puddling* or *reverberatory* furnace (fig. 6), on

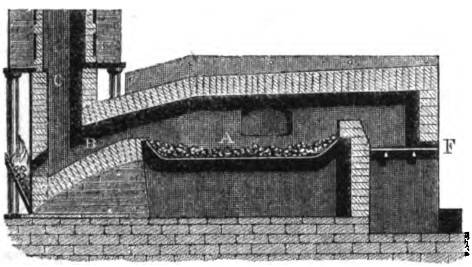

Fig. 6.

the hearth, A, of which the iron plate of fine metal, broken in pieces, is placed. In this part of the process, the fuel is not mixed with the iron, but is kept separate therefrom, and is consumed on an ordinary fire-grating, F, at the one end of the furnace. When the coals are being burned, the heat and combustible gases evolved are carried over the surface of the iron lying on the hearth, A, thence by a contracted passage, B, to the chimney, C. The result is, that the plates of iron rapidly fuse; and the hot air, as it impinges on the molten iron, combines with the impurities contained therein, and for the most part removes them. This is accomplished by the oxygen of the air (1) seizing the carbon and carrying it off as gaseous carbonic acid; (2), combining with the sulphur, and volatilising it as sulphurous acid, and uniting with the phosphorus and silicon to form phosphoric and silicic acids, which are in greater part left behind in the slag. After two to three hours' stirring or agitating, the impurities are separated, and the iron, now much less fusible, assumes a granular state, in which condition it is rolled into large balls. These balls are carried, whilst still hot, to the *forge-hammer* or *steam-hammer*, where they are repeatedly and suddenly compressed by an enormous weight, which squeezes out the remaining impurities, like water from a sponge, and leaves the pure iron. The latter is conveyed at once to a series of grooved rollers, in passing through and through which, it is rolled and re-rolled; its particles are thus compacted, and its tenacity greatly increased. By these several processes, the metal is converted from a fusible, hard, and brittle substance, to a tough and elastic bar, which is hardly fusible; and which, from its property of yielding and altering its form under the hammer, has acquired the name of *malleable* iron. There are various qualities of malleable iron, according to the processes followed; and what is strange, the most perfect processes will not bring the iron of one district up to the same standard as another, nor will the forging of one season be equal, even from the same furnace, to the forgings of another season.

At the present time (1856–7), the iron world has been startled by the announcement of a new and rapid process of purifying *cast* or *pig iron*, and obtaining therefrom *bar* or *malleable* iron, and *steel*. The patentee, Mr Bessemer, takes the liquid iron as it flows from the blast-furnace, receives it in a large covered ladle, (fig. 7), made of malleable iron, lined with loam or clay, and inserts in the molten mass a fire-clay pipe, through which air is driven with great force. The hot blast is preferred to the cold blast, but the latter will do. The oxygen of the air, as it gurgles through the molten iron, combines with the carbon and other impurities, and carries these rapidly away. The ladle being tilted round, the half-purified iron is then allowed to flow into a shallow iron trough,

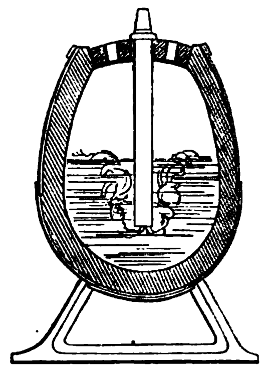

Fig. 7.

where it cools and becomes *fine metal*. This part of the operation is the equivalent of the ordinary *finery furnace*. The plate of fine metal is broken in pieces, and introduced into a *reverberatory* or *puddling furnace*, somewhat similar in shape to that ordinarily employed, but pierced with a number of openings at each side, through which fire-clay nozzles are inserted, and air —hot or cold—driven into or upon the iron, when it becomes molten. Steam is likewise introduced, especially at the commencement of the process. The air being thus brought intimately in contact with the half-purified iron, the remaining impurities are rapidly carried away. Where great purity is required, Bessemer recommends that the spent gases from the fire-grate of the puddling-furnace, which often contain sulphurous acid, should not be allowed to come in contact with the iron; and to obviate this contamination, the iron is enclosed in retorts similar to those used at a gaswork, and the air forced through the molten metal when enclosed in such.

More lately, Bessemer has suggested that the process of refining pig or crude iron should be accomplished by a single operation. For this purpose, an air-furnace is employed, in which there is placed a fire-clay or black-lead crucible, capable of holding, when three-fourths full, about seven hundredweights of molten iron. Prior to the introduction of the metal, the crucible is surrounded by fuel; and when the vessel has attained a bright-red heat, the iron is run in by a funnel inserted at the upper part of the crucible, and thereafter the tube conveying the blast is thrust in. The air, or air and steam, act on the impure iron. The free oxygen carries off the carbon as carbonic acid, and the water acting upon the iron, is decomposed; the hydrogen thereof is set free, and the oxygen combining with the iron, forms oxide of iron, which is itself decomposed by the carbon uniting with the oxygen to form carbonic oxide, and liberating the iron in the metallic condition. Besides the changes enumerated, a large amount of iron is converted into oxide of iron by the excess of oxygen thrust in. The sulphur present as impurity is burned partly away as sulphurous acid, by uniting with the oxygen of the air, and in other part is acted on by the hydrogen derived from the steam, and carried off as sulphuretted hydrogen. The phosphorus is oxidised into phosphoric acid, and in greater part is left still in the iron. After the blast has been on for fifteen or twenty minutes, the jets of flame which issue from the molten mass elongate very much, and continue so for five or six minutes, when they

subside by degrees, till they almost cease; and in thirty-five minutes from the commencement, the process is complete. During the progress of the operation, a copious discharge of slag takes place, which mostly remains as a scum on the surface of the pure iron which forms the denser and lower stratum. The tap-hole in the crucible being unstopped by driving an iron rod into the clay-stopper, the liquid iron is run into a mould or founder's ladle. For castings which require much carbon in the iron, Bessemer first refines the iron by the above operation, and then thrusts into the molten mass some wood, bituminous shale, carbonaceous matters in general, or a stream of carburetted hydrogen, till the requisite amount of carbon is obtained. Bessemer likewise lays claim to the introduction of dry carbonate of soda, and dry carbonate of potash into the molten iron by means of the air-blast, whereby the silica is more easily removed, and a slag formed.

Theoretically, the process of Bessemer is a correct one. By the older and ordinary methods, the air tardily assisted in carrying off the impurities, because it was only sparingly admitted to the iron; but without altering the agent which accomplishes the purification, he expedites the process by thrusting air in great abundance through the impure iron. Practically, however, it does not as yet seem possible by Bessemer's process to burn away the impurities, without at the same time oxidising, burning, or wasting much good iron. It appears highly probable that the great practical skill of our ironmasters will be found sufficient to surmount this difficulty, and a method be adopted whereby the admission of air in minimum quantity be so regulated, that, whilst it burns away the impurities, it will not be allowed to proceed so far as to burn the iron itself. The present system of *refining* and *puddling* iron is notoriously a primitive, time-devouring, and stationary one; and any inquiry having reference to the shortening of the number of hours required, must be of advantage at all times. The process of Bessemer is far from being a perfect one, but it is a step in the right direction, which will doubtless be carried further; and Bessemer ought to receive the thanks of the *iron world* for having given impetus to thought on the subject, which was very much wanted, and which will undoubtedly, in the hands of some one, lead to most important practical and commercial results.

Steel.—Bar-iron is converted into steel by being exposed to the action of heat in contact with carbonaceous matter. Steel is thus a peculiar stage of iron, depending on the quantity of carbon which it contains, though we are unable to give a criterion for that quantity. Pig-iron contains more carbon than steel, and steel about one per cent. more than wrought iron. Steel is therefore an intermediate step in the transition of pig to wrought iron. It has consequently been produced by melting these substances together; by which means the pig-iron has imparted to the wrought iron so much of its carbon as would serve to reduce it to a kind of steel. There are three kinds of steel: blistered steel, shear steel, and cast steel. *Blistered steel* is made by placing alternate layers of wrought iron and carbon in a furnace exposed to considerable heat. The steel thus made is found to contain small bubbles or blisters, and the process is termed *conversion* or *cementation. Shear steel* is made by choosing proper pieces of blistered steel, about 3 feet long, and 1½ inch square. Half-a-dozen of these are heated in a box with a flux, such as sand or clay, to the required pitch. These being hammered under a tilt, are welded into what is called single shear; the process performed over again gives double-shear steel. This article, properly prepared, and cast into ingots, becomes *cast steel.*

The most remarkable, as well as the most useful of the properties of steel, is the power which it has of changing permanently its degree of hardness and elasticity by being *tempered*—that is, by undergoing certain changes of temperature. No other metal is known to possess this property, and iron itself acquires it only when it is combined with a minute portion of carbon. If steel is heated to redness, and suddenly plunged in cold water, it is found to become extremely hard, but at the same time it is too brittle for use. On the other hand, if it be suffered to cool very gradually, it becomes more soft and ductile, but is deficient in strength. The process of tempering is intended to give to steel instruments a quality intermediate between brittleness and ductility, which shall insure them the proper degree of strength under the uses to which they are exposed. For this purpose, after the steel has been sufficiently hardened, it is partially softened, or let down to the proper temper, by heating it again in a less degree, or to a particular temperature suited to the degree of hardness required, after which it is again plunged in cold water. Different methods have been pursued for determining the temperature proper for giving the requisite temper to different instruments. One method, which answers sufficiently well in practice, is to observe the shades of colour which appear on the surface of the steel, and succeed each other as the temperature increases. Thus, at 430° of Fahrenheit, the colour is pale, and but slightly inclining to yellow: this is the temperature at which lancets are tempered; at 450°, a pale straw-colour appears, which is found suitable for the best razors and surgical instruments; at 470°, a full yellow is produced, suitable for penknives, common razors, &c.; at 490°, a brown colour appears, which is used to temper shears, scissors, garden-hoes, and chisels intended for cutting cold iron; at 510°, the brown becomes dappled with purple spots, which shew the proper heat for tempering axes, common chisels, plane-irons, &c.; at 530°, a purple colour is established, and at this degree the temper is given to table-knives and large shears; at 550°, a bright blue appears, used for swords and watch-springs; at 560°, the colour is a full blue, and is used for fine saws, augers, &c.; at 600°, a dark blue, approaching to black, has become settled, and is attended with the softest of all the grades of temper used only for the larger kinds of saws.

The inferior kinds of cutlery are made of blistered steel welded to iron. Tools of a better quality are manufactured from shear steel, while the sharpest and most delicate instruments are formed of cast steel. The first part of the process consists in forging, and is varied according to the kind of article to be formed. Common *table-knives* have the blade forged of steel, and welded to a piece of iron, out of which the shoulder, and part which enters the handle, are made, the shape being given to them by hammering in a die and *swage.* They are afterwards tempered and ground. *Forks* are made by forging the shank, and flattening the other end to the length intended for the prongs. The prongs are made by stamping the metal at a white heat between two dies, the uppermost of which is attached to a heavy weight, and falls from a height. The shape is thus given to the fork, leaving, however, a flat thin piece of metal between the prongs, which is afterwards cut out with a fly-press. They are subsequently filed, pointed, bent, hardened, and polished.

Blades of *penknives* are forged from the end of a rod of steel, and cut off, together with metal enough to form the joint. The small recess in which the nail is inserted to open the knife, is made with a curved chisel while the steel is hot. *Razors* are forged from cast steel, much in the same manner as knives. The anvil is commonly a little rounded at the sides, for the purpose of making the sides of the razor a little concave, and the edge thinner. In forging *scissors*, the shape is given to the different parts by hammering them upon different indented surfaces called *bosses.* The bows, which receive the finger and thumb, are made by punching a hole in the metal, and enlarging it by hammering it round a tool called a *beak* iron. The halves are finished by filing and grinding, and afterwards united by a joint.

Saws are made from steel-plates rolled for the purpose, and have their teeth cut or struck by a machine, finished by filing, and set by a suitable instrument. *Axes, adzes,* and other large tools, are forged from iron, and have a steel-piece welded on of the proper size, to form the edge.

To enable the steel to be wrought, it is brought to its softest state; but after the shape is given to the instrument, the steel is hardened and tempered by the methods already described. The remaining part of the manufacture consists in grinding, polishing, and setting the instrument, to produce a smooth surface and a sharp edge. The *grinding* is performed upon stones of various kinds, among which freestone is perhaps the most common. These stones are made to revolve by machinery, and move with prodigious velocity, so that the surface, in some cases, passes over 600 or 700 feet in a second, and stones have been burst by their own centrifugal force. For grinding flat surfaces, like those of saws, the largest stones are used; while for concave surfaces, like the sides of razors, smaller stones are used, on account of their greater convexity. The internal surfaces of scissors, forks, &c., which cannot be applied to the stone, are ground with sand and emery, applied with instruments of wood, leather, and other elastic substances. The last polish is given by a material composed chiefly of the oxide of iron. The edges are, lastly, *set* with hones and whetstones, according to the degree of keenness required. The test used by cutlers for determining the goodness of the edge and point of a lancet is, that it shall pass through a piece of soft leather without sensible resistance. *Needles* are polished by tying them in large bundles with emery and oil, and rolling them under a heavy plank till they become smooth by mutual attrition. The shape is previously given, and the eye made with a steel punch.

The uses of these three substances—cast iron, malleable iron, and steel—are so numerous and varied, that it would be impossible, even within the limits of our sheet, to give anything like a satisfactory detail. In one or other of its forms, iron is now employed for almost every purpose to which wood, or any of the other metals, can be applied in the arts of civilised life. In agriculture, architecture, ship-building, the fabrication of machinery, railways, the construction of implements and utensils, either for the objects of war or peace, and in the formation of all those articles which come under the designation of *hardwares*, its importance is pre-eminent—conferring upon Britain a wealth, power, and position which, but for the presence of her coal and iron, she could never have attained. But though iron is thus important, abundant, and common, it is by far the most difficult of the metals to bring into a state fit for use; and the discovery of the methods of working it seems to have been long posterior to the use of gold, silver, and copper. At what time it began to be made in this country, there is no means of ascertaining: ironworks are said to have been established by the Romans in the Forest of Dean in Gloucestershire; but be this as it may, it was not till a comparatively recent period that the manufacture began to assume anything like a national importance. 'Down to the seventeenth century'—we quote the *Cyclopædia of Commerce*—'the ore was entirely smelted with charcoal; and there was a considerable number of furnaces in those districts where wood and iron were plentiful, particularly the Weald of Kent, Surrey, and Sussex; but in course of time, wood-fuel becoming scarce, the trade was threatened with decay. Many attempts were made during the seventeenth and early part of the eighteenth century, to retard the decline by the use of pit-coal, but without effect; the simple hand-worked bellows, or the more powerful water-movement, which produced a sufficiency of blast for charcoal, having little effect upon coal; and the number of furnaces, which in 1619 was estimated by Lord Dudley—who in that year obtained a patent for smelting with coal—at 300, fell off towards the middle of the eighteenth century to 59. Science, however, came to the rescue of one of our greatest staple manufactures. In 1760, Smeaton erected a cylinder blasting-machine for the Carron Company, which, after some improvements, enabled the same furnace that formerly yielded 10 or 12 tons weekly, to produce 40. Shortly after this, Watt's improvement of the steam-engine, and its application to ironworks, not only revived the trade, but enabled it to distance all foreign competition. Ores that formerly could not be worked with profit, either from their inherent intractableness, or from the small proportion of metal they contained, were now advantageously submitted to the furnace, and more metal was extracted from the richest ores. Of recent inventions, by far the most important is the substitution of the *hot* for the *cold blast*, by artificially heating the currents of air impelled into the furnace. This discovery of Mr Neilson of the Clyde Ironworks, operates by obtaining a larger quantity of metal with a less degree of fuel. In 1829, with cold air, 1 ton of iron consumed 8 tons 1 hundredweight of coal; in 1833, with hot air, the same quantity of iron was procured with only 2 tons 5 hundredweights of coal.'

The result of these successive improvements and inventions presents the statistician with some of the most astonishing facts in the history of British manufactures. In 1740, the quantity of iron made in the United Kingdom did not exceed perhaps 25,000 tons; after the cylinder invention, it rose in 1796 to 124,879; in 1802, it was estimated at 170,000; in 1828, it rose to 702,584; in 1839, to 1,512,000; and at the present time, it exceeds 3,000,000 tons! It is true that the trade is subject to rapid and extensive fluctuations, the production rising and falling to the amount of several thousand tons, and the price ranging from £6 to £14, or even higher, a ton; but the immense demand now made by railways both at home and abroad—by ship-building, bridge-building, and the like—is not likely to suffer any considerable decline for several years to come. The other countries producing iron to any extent are—France, Belgium, Sweden, Saxony, Austria, Spain, and the United States; the whole furnishing an aggregate supply somewhat less than that of Great Britain, though in the last-mentioned country the trade has increased prodigiously since the application of the hot-blast to American anthracite has proved successful. At home, the chief seats of the iron trade are—Staffordshire, Shropshire, South Wales, Yorkshire, Derbyshire, and Lancashire in England; Lanarkshire and Stirlingshire in Scotland; in Ireland there are no ironworks of importance. The manufacture of hardwares, machines, engines, iron-steamers, locomotives, &c., is now more generally diffused throughout the country, though Birmingham and the towns around it still maintain their supremacy in general hardwares; Sheffield in cutlery; Manchester, Glasgow, and Dundee, in machinery; and Glasgow and Liverpool in ship-building.

Lead.

This is another of the metals which have been long and extensively used in the arts of civilised life. It has a grayish-blue colour, with a bright metallic lustre when newly cut, but soon tarnishes, and assumes a dull earthy aspect on exposure to the air. Its texture is close, like that of gold and silver; its specific gravity is about 11·45; and it is very malleable and ductile, but soft and unelastic. It is one of the least sonorous of the metals; melts at the low degree of 600° Fahrenheit; soils the fingers when rubbed; and emits a peculiar odour. Though readily oxidised by exposure to the air, the oxidisation does not proceed far; hence its durability for roofing and other external purposes. Pure or distilled water put into a clean leaden vessel, and exposed to the air, soon oxidises and corrodes it,

and delicate tests discover oxide of lead *in solution* in the water. River and spring waters do not act so readily on metallic lead, but few, if any, of the waters introduced into towns or houses for culinary purposes are *entirely* deficient in possessing a solvent action on lead. This action may only be $\frac{1}{100}$th to $\frac{1}{10}$th of a grain of lead in one gallon (70,000 grains) of water, when it may be reckoned harmless; or it may amount to a larger fraction, when it becomes dangerous to be taken into the animal system. Leaden cisterns may be used with impunity for the preservation of most ordinary spring or river waters, and the more so that the crust which forms upon the metal effectually retards all further action. As this crust partly consists of carbonate of lead, which is very poisonous, great care should be taken to prevent its diffusion through the water upon any occasion, as by scraping or cleaning the cistern. Natural waters, highly charged with carbonic acid, cannot, however, under any circumstances be kept in lead vessels, or passed through leaden pipes with safety.

Fourteen or fifteen ores of lead are known to mineralogists; but that of *galena*, a sulphuret of the metal, is the only one occurring in sufficient quantities to become an object of mining and metallurgy. It is found but sparingly in the primitive crystalline rocks, more plentifully in the transition schists and slates, and most abundantly in the transition and mountain limestones. The principal lead-mining countries are Britain; Saxony, Bohemia, and other states of Germany; Spain; France; and Missouri in the United States. The lead-mines of Britain are of great importance; and those of Derbyshire are said to have been worked prior to the Roman invasion. The most productive at present are situated in Northumberland, Cumberland, Durham, Derbyshire, Flintshire, Isle of Man, and at Leadhills in Scotland. Nearly the whole produce is derived from galena, in the proportion of about 85 per cent. of pure metal.

When lead ore comes from the mine, the first operation is to wash and sort it into heaps of different qualities; this is done either by putting the ore into a trough, and stirring it, or filling a sieve, the meshes of which are made of iron, and immersing it in a vat full of water. Another process is to put the ore upon a *grid* or screen, which consists of a number of bars of iron placed parallel to each other, about an inch apart. Over this grating, a stream of water flows, which washes away all impurities, and also separates the small pieces of ore from the large. The smaller pieces are then collected into a finer sieve, and washed again, and all pure ore which may still be amongst them is carefully picked out with an iron scraper or *crimp*. This washing is greatly facilitated by the specific gravity of the metal. The ore containing most galena sinks first, and is found next the bottom of the vat; a second quality of ore will be found on the top of this, and the inferior kinds above it. When the sieve is immersed in the water, it is shaken pretty severely, which causes the ore in a manner to float, and allows the heavier pieces to sink to the bottom. The mixed ore—that is, such as contains stone and other impurities in the lump, along with pure galena—is then sent to the grinding-mill. This consists either of a series of stampers, which pound the ore, or of a pair of fluted cylinders, through which the ore is made to pass: it is afterwards ground to the requisite fineness by smooth rollers. The mixed ore, after being ground, is again washed, and the pure galena separated from the impurities.

There are two kinds of furnaces used in the smelting of lead ore—a reverberatory furnace (see fig. 8), called a *cupola*, and the other known by the name of the *Scotch furnace*. The former, in the interior, is generally 8 feet long, 6 wide, and 2 high at the centre. The fire is placed at one extremity, and is separated from the smelting part by a wall, A, which is built about half the height of the furnace. The hearth upon which the ore is placed is composed of furnace-slags, and it slopes from the wall which separates it from the fire to the other end, B, of the furnace, and is hollowed from the sides to the centre. This is enclosed by an arched roof, in the middle of which is a small aperture for admitting the ore from a hopper, H, placed above it. The Scotch furnace is much of the same nature as the above, except that the hearth, sides, and sole-plate are made of cast iron, from two to three inches thick. The roasting is performed with peat and coke, and the furnace is urged by bellows. About 20 hundredweights of ore are usually put into the furnace at a time, which is spread equally over the hearth with a rake. For the first two hours, no regular fire is made, a gentle heat merely being kept up by putting small coal on the furnace, the doors of which are kept shut. This is called the roasting process, which is performed principally for the purpose of dispelling all sulphureous vapours from the ore. At the end of two hours, the fire is raised, and the metallic lead soon begins to flow from the ore. The smelter and his assistant now stir the ore at intervals, and a shovelful of quicklime is thrown in. This is done in order to liberate the oxide of lead from the ore, and allow it to react upon any sulphuret which may have resisted the roasting. The heat is again increased, and the stirring continued. In about four hours from the commencement, the furnace receives its greatest heat, after which a tap-hole is opened, and the lead runs into an outer basin. From this it is cast in semi-cylindrical moulds, and receives the name of *pigs* or bars.

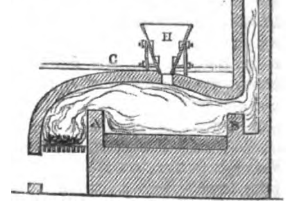

Fig. 8.

Metallic lead is employed for numerous purposes in the arts: rolled into *sheets*, it is used for roofing, lining of cisterns, tea-boxes, &c.; cast into *pipes*, it is employed for conducting of water, gas, and the like; and alloyed with arsenic, and dropped through perforated trays from lofty towers, it forms *shot* of various sizes. Alloyed with tin in different proportions, it constitutes *solder* and *pewter;* and with antimony and tin, it forms *type* and *stereotype metal*. Combined with oxygen, it constitutes *massicot*, a protoxide of a pale yellow colour; *litharge*, also a semi-crystalline protoxide, obtained in separating silver from lead ores, enters largely into the composition of flint-glass; *red-lead*, a deutoxide, is extensively employed as a pigment, and also in the manufacture of flint-glass; *white-lead*, a carbonate of the metal (see CHEMISTRY) is a well-known paint; as is also the beautiful yellow chromate; while the acetate of lead, commonly known as *sugar-of-lead*, is employed for various purposes in the arts and in medicine.

In the reduction and application of lead to the above purposes, a considerable amount of mechanical and chemical ingenuity is required. Thus, in the preparation of sheet-lead, a plate is first cast, and then subjected to successive *millings* between heavy rollers, which extend and reduce it to the desired thickness. The thickness is regulated by screw-work, which keeps the rollers apart, so as to produce a sheet varying from half an inch to the thinness of the finest writing-paper. Still greater ingenuity is exhibited in pipe-drawing. A *plug*, or thick short pipe, is first cast in a mould; a mandrel, or steel rod, of the desired bore is inserted in this pipe, which is then drawn by machinery through a succession of gradually decreasing holes in a steel-plate or die. In producing a two-inch pipe, no fewer than sixteen dies are employed, the diameters of which

descend in a regular series. The hole through the die is conical—that is, larger on one side of the die than on the other; and the lead enters the hole at the widest part, whereby a process of compression is undergone; but at a certain point in the operations, a *cutting-die* is introduced—that is, one wherein the lead is at once exposed to a cutting-edge, the result of which is, that a thin film is cut or scraped from the whole surface of the pipe. The elongated pipe is now removed from the mandrel, coiled up, and sent to the plumber. By this process, lead-pipes of good quality are obtained, but in lengths of only 20 to 30 feet; and where longer lengths are required without a join, recourse is had to the hydraulic pipe-press. This machine contains lead in a molten state; and by means of a piston-rod worked by a hydraulic press, the molten lead is forced through a mould the exact size of the pipe required. As the pipe escapes from the press, it is coiled round a drum, and can be obtained of almost any length.

Shot is formed by dropping an alloy of lead and arsenic through perforated trays or colanders, from the top of lofty towers, into a cistern of water beneath; the same result is more economically obtained by dropping the metal from the surface to the bottom of some waste coal-shaft, as is done at Newcastle. The perforations of the colanders are of sizes ranging from $\frac{1}{6}$th to $\frac{1}{30}$th of an inch in diameter; and on passing through these, the melted metal assumes a globular form, cools partially in falling, and ultimately settles in the cistern in drops less or more spherical. These are next assorted by being passed through sieves, which retain all imperfect forms; and still further, by being passed over an inclined plane of polished iron, when the well-shaped shot descend with an impetus sufficient to carry them into a trough at some distance from the end of the incline, while the imperfect forms travel slowly, and drop 'dead,' as the workmen express it, almost over the verge of the plane. The dark glossy hue of shot is obtained by churning it with powdered black-lead in revolving cast-iron barrels, a process which also assists in producing a still more spherical form. Leaden bullets are cast in moulds; but all the former modes of casting, cutting, and rolling shot are now abandoned. None of the chemical preparations of lead involve any peculiar difficulty either in their manufacture or application; the only contingent evil is their poisonous character, which manifests itself more or less on the constitutions of painters, plumbers, whitelead-makers, and the like. Lead, indeed, is a metal requiring very cautious use in any form, and ought to be avoided in the manufacture of all culinary, dairy, brewing, and other utensils employed in the preparation of human food.

The amount of lead annually smelted in Britain is estimated at 48,000 tons or thereby; which, at the present price, would make the value of the produce little short of £1,000,000 sterling. About 15,000 tons are annually exported, partly in pigs, and partly in sheet, shot, red-lead, and litharge.

Zinc.

Though known as early as the beginning of the sixteenth century, the numerous and important applications of zinc, or *spelter* as it used to be called, are for the most part of very recent date. Its distinguishing characteristics are bluish-white colour and lustre; specific gravity, 6·89; at common temperatures, tough and intractable; but heated to between 220° and 320° Fahrenheit, it becomes malleable and ductile, so that it may be hammered out, rolled into sheets, perforated, and even drawn into wire of such tenacity, that $\frac{1}{18}$th of an inch in diameter is capable of sustaining a weight of twenty-six pounds. Heated beyond that point—say between 400° and 500° Fahrenheit—it again becomes so brittle, that it may be reduced to powder in a mortar. It melts at 773°; and heated beyond this, it takes fire in the open air, and burns with a brilliant bluish flame. The metal is obtained from two ores—namely, *calamine*, a native carbonate; and *blende*, or *black jack*, a native sulphuret. These ores occur in two geological positions—namely, either in the carboniferous or in the magnesian limestone, associated with galena, and sometimes with the ores of cadmium.

Zinc ores are found in Britain, especially in Flintshire, Derbyshire, and Cumberland; but the quality of the British metal is inferior to that of Germany, from whence, *vià* Hamburg, about 170,000 hundredweights are annually imported, commonly as ballast for ships bringing wool. Of this amount, about one-half is kept for home consumption, and the remainder for exportation, chiefly to India, which, previous to 1820, obtained her supply from China. The ores are roasted and mixed with charcoal; the mixture is put into a kind of crucible, closed at top, and perforated at bottom by an iron tube, which passes through the grate of the furnace into water; and the vapour of the zinc distils downwards through the tube, and is condensed in the water. The first portions are impure, containing arsenic, and often cadmium, in which case the vapour burns with what the workmen call a *brown blaze;* when the *blue blaze* appears, the zinc is collected. The above is the English method of reduction; in Germany and the Netherlands, the principle is much the same, but somewhat differently applied.

Zinc being a cheap and light metal, and one which, when superficially oxidised, long resists the further action of air and water, it is now employed as a substitute for lead in lining cisterns and baths, covering roofs, forming water-spouts, and the like. It has also been used of late in the manufacture of kitchen and dairy utensils. It is likewise wrought into buttons and other small-wares; and zinc-plates have been a considerable while in use in the transfer of printing, under the title of *zincography*. Its sulphate and oxide are employed in medicine; and with copper it forms, as already described, the well-known alloy, brass. Though the action of water upon zinc be scarcely appreciable, after it has once been coated with the oxide, yet the addition of a little acid—as sulphuric—dissolves and removes this coating, and further oxidation proceeds with rapidity. It is this action which renders zinc so powerful a generator of electricity in the voltaic pile or battery. (See Voltaic Electricity.)

Aluminum.

This metal has recently been introduced before the public as one which is likely to be employed in our arts and manufactures on a large scale. It was reserved for M. Deville of the chemical works of Javel to suggest a mode of preparation by which this metal could be economically prepared. The process he follows is to act on chloride of aluminum by means of sodium. The chloride of aluminum is artificially prepared by passing chlorine gas through a layer of alumina and coal-tar previously calcined, and contained in a gas-retort. The chloride of aluminum volatilises, and condenses in a receiving chamber lined with glazed fire-brick, as a compact substance of considerable density and sulphur-yellow colour. It may be purified from iron by volatilising it a second time, and allowing the vapour to pass through a tube heated to 750° Fahrenheit, and studded with points of metallic iron. The latter arrest and fix the vapours of perchloride of iron, and allow to pass only the pure chloride of aluminum, which passing into a condensing arrangement, is deposited in colourless and transparent crystals. The pure chloride of aluminum is mixed with sodium introduced into metallic tubes and heated, when the sodium seizes the chlorine to form chloride of sodium—common salt—and sets free the aluminum. The experiments of Deville were conducted on a large scale, at the cost of the Emperor of France; and the trials shewed that the production of aluminum in quantity was quite practicable, and was not very costly. This inquiry has likewise been of great service, as it has

placed at the disposal of scientific men the metal sodium at a mere fraction of the price previously paid for it.

Aluminum is a white metal, somewhat resembling tin in external appearance, but with a much less specific gravity. It is not tarnished when exposed to air; even when raised to a high temperature, it is not oxidised; so that it may be regarded as unalterable. It possesses remarkable sonorous properties, and in this respect is not outrivalled by the most sonorous alloys, such as bell-metal. No other single or pure metal possesses the sonorous character in an unmixed or unalloyed condition. Aluminum appears likely soon to rank as one of the most useful and serviceable of the metals. It has already been manufactured into medals, trinkets, and watch-wheels of exquisite workmanship; and from its great lightness and unalterable character, it is now—1857—being made into eagles to surmount the standards in the French army, in preference to the other metals which are much more dense, and are more liable to be tarnished. The non-tarnishing property of aluminum is even carried into its alloys. A compound of seventy-five parts of iron, and twenty-five parts of aluminum, will not oxidise or rust in damp air, though the iron by itself rapidly does so.

Tin.

Tin was known to the ancient nations of the Levant, who obtained it chiefly from Spain and Britain. It is a white, brilliant metal; has a slight taste and smell when rubbed; is malleable to a considerable degree, but is inferior in ductility and tenacity. Its hardness is intermediate between that of gold and lead; its specific gravity is about 7·3; it melts at 442° Fahrenheit, and at a white heat takes fire and burns with a bright flame. It oxidises but slowly on exposure to air and moisture; hence its value in coating or tinning more oxidisable metals, as iron. Tin is rather a rare metal; and is principally found in primitive rocks, where it occurs chiefly in veins, but partly also disseminated, and in beds. There are only two ores of the metal known—the double sulphuret, which is rare; and the native peroxide, from which the commercial supplies of the metal are obtained.

This latter ore is found abundantly in Cornwall and the western district of Devonshire; in Germany, Bohemia, and Hungary; in Chile and Mexico; and in Malacca and Banca in the East Indies. The tinstone of Britain is chiefly obtained from mines; but considerable quantities are sometimes discovered in alluvial soils—the débris of rocks in which the ore was originally imbedded. Repeated washings, by means of running water, being the chief process by which the ore is separated from such débris, the name of *stream-work* is commonly applied to this method of obtaining it. On one occasion, the water being excluded from a branch of Falmouth harbour, a bed of rounded masses of tin-ore, from two to ten feet thick, was found fifty feet below a bed of alluvium—£50,000 is said to have been made by this discovery.

The ore, in whatever way obtained, is first broken into small fragments, then pounded in stamping-mills, washed, sifted, and roasted. It is next reduced by smelting with coal and a flux of lime, under a very strong heat, which is kept up for eight or nine hours. The liquid tin, on being run off from the slag, is still mixed up with iron, arsenic, and other impurities, and has to undergo fresh smeltings, after which it is cast into granite moulds, capable of containing about three hundredweights each. In this form it is known as *block* or *bar tin*—a term generally used in contradistinction to *grain-tin*, which is obtained from stream-ore, somewhat differently treated. After the stream-tin ore has been dressed and pounded, it is smelted with wood-charcoal, run off into iron vessels, and there kept liquid by a gentle heat, till, by repeated agitation with pieces of charcoal, all impurities are expelled. It is finally removed by ladles, and poured into small moulds. The grain or stream tin so obtained is of superior quality, and is employed by dyers, and for the finer purposes.

The uses of tin are both numerous and important. Besides being employed in the formation of a variety of utensils, it is largely used in *tinning* copper and iron-plate, to protect them from rust—an art which originated in Saxony, and was made known in Britain about two centuries ago. It consists in carefully cleaning the surface of the plate with sal-ammoniac, or with hydrochloric (muriatic) acid, rubbing it well, and then immersing it in melted tin, by which it acquires a thin and equable coating. Vessels are coated internally by heating them, pouring in a certain quantity of melted tin, and then rotating them, so that the tin may come in contact with every part of the surface. Alloyed with antimony, copper, bismuth, and lead, tin forms *pewter;* it enters into the composition of *bell-metal*, *type-metal*, and *solder;* it is used in the process of enamelling; in silvering, or rather tinning, looking-glasses, in coating pins; by dyers and calico-printers as a *mordant* when dissolved in hydrochloric acid; largely in the form of *foil* or leaf, which is made by beating; its oxide is much used in polishing, under the name of *putty-powder;* and the *purple of Cassius*, so called from its inventor, is a union of protochloride of tin with perchloride of gold.

The annual produce of the British tin-mines is estimated at 4000 tons, worth from £65 to £80 a ton. About 1500 tons of unwrought tin are annually exported, principally to France, Italy, and Russia; and this, exclusive of tin, pewter-wares, and tin-plate, to the value of £400,000 yearly, sent to the United States, Italy, Germany, France, the colonies, &c. The amount of crude tin brought from the East is very variable, ranging generally between 500 and 1500 tons per annum.

Mercury or Quicksilver.

This is a well-known metal, of a brilliant silver-white colour, fluid and mobile at ordinary temperatures; hence the name *live*, or *quick*, silver. In this property of fluidity, it differs from all other metals—never being solid, unless when subjected to a degree of cold equal to —39° or —40° Fahrenheit. In this condition it has been obtained by arctic explorers, who, under extreme depressions of temperature, found their barometers and thermometers useless, and who, for curiosity's sake, have shot bullets of it from their muskets. When solid, it is found to be malleable, a fact of no practical importance, however, as it instantly passes into the fluid state on being brought to a higher temperature than − 40°: it boils and vaporises at about 600° Fahrenheit. Its specific gravity is about 13·59; thus ranking above all other metals, with the exception of platinum, gold, and tungsten. It is found native in small quantities—that is, in minute dewy globules; but for commercial purposes it is always extracted from the ore called *cinnabar*. This ore is a sulphuret of the metal, of a red colour—except in the hepatic variety, which is gray—massive and crystallised, occurring in veins, and distributed variously through the matrix of the veinstone. It is found but sparingly in the primitive rocks; the principal deposits of the mercurial ores being, in all parts of the world, in the middle secondary strata—that is, in the upper portions of the coal-measures, and in the magnesian limestone and new red sandstone. In these formations the ore occurs either in irregular veins, or is combined with the sandstones, bituminous schists, and indurated clays.

The most productive mines of cinnabar are those of Almaden, near Cordova, in Spain; of Idria in Austria; of Huancavelica in Peru, at an elevation of 14,500 feet above the sea; and of New Almaden in California. Quicksilver is also produced in several of the Chinese provinces, and sparingly in one or two localities in Rhenish Bavaria, Bohemia, and Hungary. The mines of Idria, which were discovered in 1497, yield annually about 150 tons of the pure metal; but could readily

supply four times that amount, were it not for certain absurd restrictions imposed upon the produce by the Austrian government. The veins at Almaden, which range from twelve to twenty feet in thickness, have been worked for nearly 3000 years; at all events, Pliny records that the Greeks imported red cinnabar from Spain 700 years before the Christian era, and that Rome in his time annually received 700,000 pounds from the same province. The usual method of reducing the ores is by distillation. The minerals brought out of the mine are broken up, picked by women and children, pulverised, and sometimes washed. In some places, the richer ores are separately burnt; but it is more usual, and considered more economical, to mix the richer with the poorer ores, and expose the whole mass together to the action of heat in closed retorts, which also contain a certain proportion of limestone. The retorts, filled with the mixture of mercury, ore, and lime, are ranged, to the number of twenty or more, in a furnace, where heat is applied. Each retort communicates with a vessel of water, in which the vapours of the mercury are condensed. In the mines of Idria, a ruder method is adopted: the ores are roasted in a kind of oven, and the vapours ascend into condensers, where the little drops of mercury collect, and are conducted into a porphyry vessel placed to receive them.

The imports of mercury into this country, chiefly from the mines of Almaden, are about 2,200,000 pounds annually, of which little more than an eighth are retained for home consumption. The remainder is re-exported, principally to South America, Mexico, the United States, and the East Indies; while smaller shipments are made to Russia, Belgium, and other countries. During the war, when the intercourse between Europe and America was interrupted, the price of quicksilver rose to such a height in the latter country that it answered to import it from China. From the peculiar character of the metal, it is transported either in iron bottles, in small leathern bags, or, as from China, in short joints of the bamboo. Mercury is often adulterated by an admixture of lead, bismuth, zinc, and tin; in which state it is less lustrous, becomes covered with a whitish film, and is not so mobile, or readily divisible into minute globules.

Mercury is principally employed for *amalgamation* with other metals, chiefly gold and silver, so as to extract them from their ores; and it is almost solely for this purpose that it is imported into South America and Mexico. It is used also in gilding, in silvering mirrors, in filling thermometer and barometer tubes, in various philosophical apparatus; and in chemistry it furnishes the only means of collecting, in the pneumatic trough, such gases as would be absorbed by water. In medicine, it is employed in several forms: the whitish insipid powder termed *calomel* is the subchloride of mercury; and the acrid, nauseous, white substance known as *corrosive sublimate* is the perchloride. This sublimate has been applied as an antiseptic in the prevention of the dry-rot in timber, of the mildewing of sailcloth, and the like. Mercury is also used in the making of *vermilion*, that beautiful pigment being prepared from an artificial cinnabar, composed of eight parts of mercury and one of sulphur. When sulphur and mercury are triturated together in a mortar, the former gradually disappears, and the whole assumes the form of a black powder, denominated *ethiops mineral;* if this powder be heated red-hot, it sublimes, and on a proper vessel being placed to receive it, a cake is obtained, of a fine red colour, which, when reduced to powder, forms the vermilion of commerce. An amalgam of mercury and silver is used by dentists for stopping hollow and decayed teeth.

Antimony.

This metal was discovered by Basil Valentine in 1490, and has since been extensively employed in medicine, in the composition of printing-types, stereotype-plates, music-plates, and the like; and also in the manufacture of the white-metal utensils now so generally used as substitutes for silver. When pure, it is of a silver-white colour, is brittle, has a specific gravity of 6·8, and melts readily at a red heat. When heated in open crucibles, it gradually combines with the oxygen of the atmosphere, and flies off in the form of a white vapour. The oxides and salts of antimony are used in medicine, their general effects being purgative, sudorific, and emetic. The metallic ore of commerce contains sulphur and other impurities, and is much more easily fused than the pure metal, which has a hardness about that of gold. Its tenacity is also considerable—a wire of $\frac{1}{10}$th of an inch in diameter being capable of supporting a weight of ten pounds.

Antimony ore is found at Rosenau in Hungary, in Saxony and the Harz, in Spain, France, Siberia, Mexico, the Indian Archipelago, and in Cornwall and Ayrshire in Great Britain. It is usually of a lead-gray colour, is crystallised, possesses considerable splendour, and is very apt, by the uninitiated, to be mistaken for an ore of lead. *Crude* antimony is the name given in commerce to the sulphuret of the metal, after being separated from the impurities of the ore by fusion with charcoal; and *regulus* of antimony is the pure metal, after being separated from the sulphur, by being mixed with tartar and exposed to heat. The powder of the sulphuret is very black, and was employed by women in ancient times to stain their eyebrows and eyelids.

Antimony is never applied to any useful purpose as an independent metal, in consequence of its brittleness and liability to corrosion; but it forms several valuable and extensively employed alloys. Thus, alloyed with lead, in the proportion of 2 to 6, with greater or less proportions of copper or tin, it constitutes the metal used for printing-types; mixed with lead alone, the compound forms the rather brittle plates upon which music is engraved; and an alloy of 112 lead, 18 antimony, and 2 block tin, forms a convenient stereotype metal. These alloys have the property of expanding as they cool; the consequence of which is, that the types come out of the moulds with sharp and well-defined edges. Hard pewter is made of 12 parts of tin and 1 of antimony; and the Britannia or white metal spoons and tea-pots, now so much in use, are composed of 100 tin, 8 antimony, 2 bismuth, and 2 copper. Antimony also unites with iron, forming a hard whitish alloy; and the smallest portion fused with gold renders that otherwise soft and ductile metal brittle and unmalleable. The manufacturer of pastes or factitious gems employs the oxide of antimony to give colour to his so-called beryls, Oriental topazes, and yellow diamonds. Six parts dry nitrate of potash, two sulphur, and one sulphuret of antimony, reduced to a fine powder, form the blue or Bengal light used as a signal at sea.

Bismuth.

This metal is of a brittle crystalline texture, reddish-white in colour, and fusible at the temperature of 497°. Its hardness is between that of copper and lead; it is scarcely malleable, breaks under the hammer, and cannot be drawn into wire. Bismuth is by no means a common metal, and is usually obtained in a combined state in Cornwall, France, Bohemia, Saxony, and Sweden. As met with in commerce, it is generally mingled with impurities of iron, arsenic, or other metals.

It is used as a *flux*—that is, for communicating fusibility to other metals; *solder*, for example, consisting of 1 bismuth, 5 lead, and 3 tin—an alloy which melts at a lower temperature than lead. It is also employed in the formation of some kinds of pewter, printers' types, and various metallic mixtures. Eight parts of bismuth, 5 of lead, and 3 of tin, constitute the fusible metal sometimes called Newton's, from its discoverer, which melts at little more than 200°, or under the heat

of boiling water, and may be fused over a candle in a piece of stiff paper, without burning the paper. A small addition of mercury aids the fusibility; and such alloys are sometimes used in taking casts of anatomical preparations. Bismuth forms the basis of sympathetic ink; and the powder called *pearl-white*, used in medicine, is obtained from the nitrate of the metal, which, when dropped into water, falls down as a white powder insoluble in water. The nitrate has also been employed as a mordant for lilac and violet dyes in calico-printing. Some of its forms seem likewise to be employed in the preparation of cosmetics, for a story is told of a lady, who, on visiting one of the watering-places in Germany, emerged from the bath as a 'lady of colour,' the chemical action of the mineral water having turned almost to blackness a cosmetic containing bismuth which had been previously applied to the face.

Cobalt.

Cobalt is a reddish-gray brittle metal, somewhat soft, fusible at a temperature a little below that required for the fusion of iron. The finest ores are found in Saxony, where it received its name (*kobold*, a devil); a term applied to it by the miners, who considered it unfavourable to the presence of the more important metals. It is never employed in the arts in the metallic or separate state; but the impure oxides of the metal, called *zaffre* and *smalts*, are extensively used as colouring materials.

The oxide of cobalt is an invaluable article in the manufacture of porcelain and pottery; all the blue colours of which are derived from that substance. When fused with glass, it communicates a blue tint to that material, without impairing its transparency; and what is especially valuable, this colour is not impaired by very high temperatures. So great is the colouring power of oxide of cobalt on vitrifiable substances, that 1 grain gives a full blue to 240 of glass! Cobalt blue, or Thenard's blue, is a beautiful pigment, prepared from the phosphate of cobalt, and which may be employed by decorative painters and artists as a substitute for ultramarine. Smalts, of which we annually import about 146,000 pounds, are prepared principally in Norway and Germany, by melting oxide of cobalt with silicious earth and potash. Zaffre, of which we import more than double that amount, is manufactured chiefly in Saxony and Prussia.

Nickel.

This metal is of a brilliant white colour, resembling silver; ductile and malleable, and capable of receiving a high polish. It is difficult of fusion, but melts at a lower temperature than iron: it undergoes little or no change by exposure to air and moisture. It is found in all meteoric iron; but its principal ore is a copper-coloured mineral found in Westphalia, and called *kupfer-nickel;* nickel being a term of detraction used by the German miners, who expected from the colour of the ore to find that it contained copper. The cobalt ores are the most fruitful sources of this kupfer-nickel, or *speiss*, which is reduced to the metallic state by roasting, dissolving, evaporating, and other processes. Alloyed with copper, nickel forms argentane, or German silver; and since this compound became an object of commercial importance, the extraction of the metal has been undertaken upon a considerable scale. It is also employed in potteries and in the manufacture of porcelain. It is, to a certain degree, susceptible of magnetism, and mariners' compasses might be made of it. The alloys of nickel, from their whiteness, hardness, and infusibility, form excellent bases for the manufacture of electro-plate.

Arsenic.

This metal, discovered by Brandt in 1733, is exceedingly brittle, of a strong metallic lustre and white colour, running into steel-gray. Its specific gravity is 5·67; when heated, it volatilises, emitting a strong odour of garlic before it fuses, and is readily inflammable. The pure metal is so brittle that it may be easily reduced to a very fine powder by trituration in a mortar. The *arsenic of commerce* is the white oxide of the metal, or, more accurately, *arsenious acid*—a compound which is obtained chiefly from Bohemia and Saxony, in roasting the cobalt ores for making zaffre, and also by sublimation from arsenical iron pyrites. Arsenious acid is originally prepared in cakes, brittle, white, faintly sweetish in taste, and more or less translucent; for medicinal purposes, these cakes undergo sublimation, in order to get rid of sulphur and other impurities. In the shops, it is usually sold in the form of a white gritty powder.

Arsenious acid, though one of the most virulent poisons, is used in medicine, forming a notable ingredient, for example, in what are called ague-drops. It is also present as an ingredient in *Scheele's green* and other dyes, in the manufacture of flint-glass, and is employed in rare instances by candlemakers, to impart to their candles a white and waxy appearance. With sulphur, arsenic forms two compounds, known in commerce by the names of *realgar* and *orpiment;* the former a red sulphuret found in Bohemia and Saxony, and used as a pigment, as well as in pyrotechnical compositions; and the latter a yellow sulphuret, found native in China, South America, &c., and produced artificially in Saxony, and employed in dyeing and calico-printing. The finer native varieties are reserved for artists.

'It is often said,' observes Mr Brande, 'that the bodies of persons poisoned by arsenic are very prone to putrefaction; but this is not always the case. After death, the stomach and bowels are usually found inflamed, but often slightly so; and it appears, from Sir Benjamin Brodie's observations, that this poison kills by some peculiar action upon the heart and nervous system. The treatment of persons thus poisoned, consists in promoting vomiting by an emetic, composed of a solution of twenty grains of sulphate of zinc in two ounces of water, aided by copious draughts of warm barley-water or gruel; but the most effective means of getting rid of the arsenic is by the use of the stomach-pump, which, when immediately resorted to, has often saved the patient. The only ready means of ascertaining the presence of white arsenic is by heating the suspected substance upon a red-hot coal, or in the flame of a candle, when it will emit the peculiar arsenical odour resembling that of garlic; but the treatment of persons poisoned by arsenic, and its detection in doubtful cases, must be left to the medical man and the chemist. It is impossible too strongly to represent the evil which results from the unfettered sale of arsenic, and from the unwarrantable use of it as a poison for rats and as a veterinary remedy; for it is thus that it finds its way into culinary vessels, gets accidentally mixed with articles of food, and that bottles which have contained it are used for beer, wine, and other beverages. Its sale should be rigidly prohibited by all save regularly qualified druggists.'

Platinum.

Platinum, or platina, was unknown in Europe till about the middle of the last century, when it began to be imported in small quantities from South America. It is of a whitish silvery colour; hence its name, from the Spanish word *plata*, silver. It is the heaviest, the most difficult of fusion, the most ductile, and the most flexible of the known metals, having a specific gravity of 21·5, and capable of being hammered into leaves, or drawn into wires, of extreme tenuity. Its hardness is intermediate between that of copper and iron; and though very infusible, it is malleable, and capable of being welded at a white heat, either one piece to another, or to a bit of iron or steel. It is not in the

least affected by the action of air or water, and is not attacked by any of the pure acids; but is dissolved by chlorine and nitro-hydrochloric acid (*aqua regia*). In ductility and indestructibility, it is hardly inferior to gold. When a perfectly clean surface of platinum is presented to a mixture of oxygen and hydrogen gas, it has the extraordinary quality of causing them to combine, so as to form water, and often with such rapidity as to render the metal red hot.

Platinum attracted little notice until the mode of purifying it and rendering it malleable was discovered by Dr Wollaston. It is found in the metallic state in Brazil and Peru; at Antioquia in South America; in Estremadura in Spain; and latterly, in considerable quantities, in the Uralian Mountains. Its appearance, in the rough state in which it is imported, is that of small grains or scales, of a metallic lustre, darker than silver, and extremely heavy. In this state it is combined with palladium, rhodium, titanium, iron, gold, or other metals. The particles are seldom larger than a pea, but pieces have been found as large as a hazel-nut; and in 1831, a mass of native metal was discovered in Demidoff's gold-mines in Russia, weighing upwards of twenty pounds!

The perfection with which vessels of platinum resist the action of heat and air, of most of the acids, and of sulphur and mercury, renders them peculiarly valuable in many chemical applications; so that notwithstanding the high value of the metal, which is between four and five times its weight of silver, it is now much employed for crucibles (fig. 9), retorts for the distillation of sulphuric acid, mirrors for reflecting telescopes, by gunsmiths, and others. Its property of being welded, either one piece with another, or with iron and steel, admits of many useful applications in the arts. From its scarcity and indestructibility, it has been proposed to use it for coinage; and such coins of the respective values of 3, 6, and 20 silver rubles are now current in the Russian Empire.

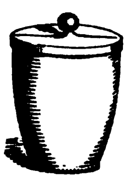

Fig. 9.

Manganese.

This is a very brittle metal, of a dusky white colour, and without either malleability or ductility. The substance known in commerce under that name, however, is the peroxide, or the black oxide of the metal. It occurs native in the Harz Mountains, in Piedmont, in the Mendip Hills in Somerset, and the counties of Devon and Aberdeen. It is found in a variety of forms: most commonly it is of an earthy appearance, and mixed with other ingredients; but sometimes in crystals of a black colour and metallic lustre. This mineral was described by Scheele, in 1774, as a peculiar earth; but in the same year, Gahn shewed that it was the oxide of a true metallic substance. The metal separately is of no known use, but the binoxide is a source of oxygen, and is largely employed in the decomposition of common salt for the production of chlorine for bleaching. It is also used by potters and glass-makers as a glaze or pigment; and lately, it has been used in calico-printing as the source of certain brown colours. Still more recent investigations have shewn that a certain proportion of manganese added to steel manufactured from British iron, produces a cast steel nearly equal to that obtained from Swedish iron. The ore of manganese, known in England by the name of *black wadd*, is remarkable for its spontaneous inflammation with oil. The pure metal can only be kept in closely stoppered bottles, under naphtha, like potassium; because, when in contact with air, it is rapidly oxidised, and falls into a dark-brown powder.

Chromium.

Chromium—from the Greek word *chroma*, colour—discovered by Vauquelin in 1797, is a metal resembling iron in colour, brittle, and difficult of fusion. It is rarely to be found in its metallic state; but several of its compounds, as chromate of iron and chromate of lead, are well known in commerce. The former, a compound of oxide of chrome with oxide of iron, is found in Unst in Shetland, in France, and near Baltimore in America. It appears massive, or in crystals of a dark colour and imperfect metallic lustre. It is employed in the manufacture of chromate of potash, a yellow salt, largely manufactured for the use of calico-printers. Chromate of lead is found native in the gold-mines of Berezov in Siberia, in the Ural Mountains, and in Brazil, and is easily prepared, by mixing chromate of potash with a soluble salt of lead. It occurs massive and crystallised, of a deep orange-red colour; but when reduced to powder, it becomes orange-yellow. It forms an excellent pigment, and is used both in oil and water-colours, in calico-printing, and in dyeing. The other compounds chiefly in use are the *oxide of chromium*, employed to give a green colour to glass and to porcelain; and *chromic acid*, which, from its property of destroying most vegetable and animal colouring matters, is advantageously employed in calico-printing. It is this acid which gives colour to the ruby; and the green of the emerald is owing to the oxide of chromium.

Cadmium.

This metal was discovered by Professor Stronmeyer of Göttingen about the beginning of 1818. It occurs chiefly in Silesia, combined to the extent of between 2 and 11 per cent. with several ores of zinc, and is reduced to the metallic state by a somewhat complicated process of solutions and precipitations. The pure metal has the colour and lustre of tin, and is susceptible of a fine polish. It is soft, easily bent, filed, and cut, and soils like lead any surface rubbed with it. It is harder and more tenacious than tin, and emits a creaking sound, when heated, like that metal. It is very ductile, and may be drawn out into fine wire, and hammered into thin leaves without cracking at the edges. Its specific gravity is somewhat less than 9; it is very fusible, melting at a point much below redness. Its scarcity prevents its employment in the arts; but it has been sparingly used in dentistry. The sulphate of cadmium has been applied to the eyes for removing specks from the cornea.

Palladium.

This rare substance was discovered in 1803 by Dr Wollaston, when experimenting on the ores of platinum, which it greatly resembles in colour and lustre. A native alloy of gold with palladium is found in Brazil, and imported into England. The pure metal is ductile and malleable, has a specific gravity of 11·5, and its fusibility is intermediate between that of gold and iron. It is oxidised and dissolved by nitric acid; its properties, however, are yet imperfectly known, nor is it, so far as we know, applied to any economical purpose, unless sometimes for the graduated scales of astronomical instruments. The Wollaston medal of the Geological Society of London is very appropriately made of palladium.

Rare Metals.

The remaining metals—osmium, iridium, tungsten, molybdenum, rhodium, vanadium, &c.—have not as yet been applied to any economical purpose. Even were they less rare, so far as their properties have been determined, they would not afford any advantage which may not be obtained by the use of the ordinary metals. As elementary substances, the reader will find details of their history, nature, and properties in the article CHEMISTRY.

THE STEAM-ENGINE.

AS introductory to the historical and practical details of our subject, we propose giving a few remarks on the nature and properties of steam, and of the value of the different kinds of fuel used in producing it. These being understood, the reader will be prepared to follow us when describing the steam-engine as applicable to the various purposes of the arts and manufactures, its construction, its operation, and economical management.

In connection with the theory of the steam-engine, the consideration of the nature and properties of water, which forms the grand agent in its operation, is a matter of some importance. For general remarks on this subject we beg to refer our readers to Nos. 31 and 32; proceeding to notice here the special points connected with it which have an immediate reference to our present subject.

Water is a fluid at ordinary temperatures, but may become *solid* on the one hand, or *aëriform* on the other, by changes in the amount of caloric (heat) with which it is supplied. These two remarkable changes in the condition of water occur at specific temperatures: it becomes solid at 32° Fahrenheit, and passes off in the state of vapour or steam when the temperature is raised to 212°. On the fluid being cooled down to 32°, it becomes ice—this temperature being named the *freezing-point* of water. When the temperature is increased so that the thermometer indicates 212°, or the *boiling-point*, the water becomes steam or vapour, assuming that condition in which its elastic force is applied to act as a moving power.

It is with the properties of this steam or vapour that we have now to do. The vapour of water, unlike other gaseous bodies, does not retain permanently its aëriform condition; this being alone dependent upon the continuation of the high temperature which formed it. By reducing this, the vapour ultimately assumes its former condition of water. Hence is obtained one of its valuable properties, so useful in the steam-engine, in one of its principal forms—namely, its *convertibility from the form of vapour into that of water*.

The second property in steam to be noticed is its *expansibility*—the vapour occupying 1728 times the space of that occupied by the water from which it is raised; this, however, presupposes the steam to be raised at the ordinary pressure of the atmosphere, and the boiling-point to be consequently at 212°. As with other gases, the degree of expansibility of steam is regulated by the pressure to which it is subjected. Thus with a pressure of 18 pounds on the square inch, the bulk of steam, as compared with that of the water from which it is produced, is 1411; with a pressure of 20 pounds to the inch, 1280 times; with a pressure of 25 pounds, 1043; with a pressure of 30 pounds, 880; 35 pounds, 766; 40, 679; 45, 610; and with a pressure of 50 pounds to the inch, 550: these proportions being approximative. This expansive property of steam, from which is deduced the law, that its pressure varies with its bulk, is another of the valuable properties which is taken advantage of in one modification of the modern steam-engine.

The third property of steam now to be described is that of its *elasticity*. In consequence of this property, it tends to free itself from the space in which it is confined, expanding in so doing in bulk or volume. The degree of elasticity, or the force of steam, is dependent on and regulated by the temperature under which it is raised. Thus, at the ordinary temperature of boiling water, the pressure which it exerts is, in round numbers, 15 pounds to the inch; when the temperature is increased to 250°, the elastic force is 30 pounds to the inch, or, as it is termed, steam of two atmospheres. The following tables shew the elastic force of vapour from 32° to 212°, and from 275° to 359°:

Temperature.	Force of Vapour in Inches of Mercury.
32°	·200
50	·375
80	1·00
100	1·86
150	7·42
180	15·15
200	23·64
212	30·

Temperature.	Elastic Force.	Pressure Square Inch.
275°	3 atmospheres, or	45 lbs.
307	5 "	75 "
332	7 "	105 "
351	9 "	135 "
359	10 "	150 "

From these it will be seen that the elastic force of steam increases in a much faster ratio than the temperature at which it is generated. Thus, 212° gives 15 pounds to the inch; 250° gives 30 pounds—an increase of 38° doubling the pressure.

The accompanying table gives the correspondence observed between the temperature at which the water boils, the density of the steam generated, and the force or elasticity it possesses in inches of mercury and atmospheres:

Temperature Fahrenheit.	Sp. gr., air at 60 Degrees being 1.	Pressure in Inches of a Column of Mercury.	Pressure in Pounds on the Square Inch.
212°	0·484	30·	14·7
222	0·553	35·00	17·15
233 ·80	0·687	45·00	22·05
242 ·50	0·81	52·50	25·725
250 ·20	0·915	60·00	29·4
274 ·70	1·33	90·00	44·1
320 ·60	2·5	180·00	88·2
350 ·00	3·61	270·00	132·3
450 ·00	10·75	900·00	441·

From these tables, it is apparent that there is an invariable correspondence between the force of the vapour of steam and the temperature at which it is generated; hence the one may be given as the rule of the other. For instance, if it is required to know the force with which the steam is working in any machine, the thermometer, which is preserved in a case air-tight, and introduced into the boiler where the steam is generated, will indicate the temperature of the water, or of the steam (for they are always the same; that is, at whatever temperature water boils to afford steam, the steam so produced is of the same temperature). On ascertaining, then, the temperature by a reference to the table, we find the corresponding force of the elastic vapour (the steam). An example will be sufficient to shew this most clearly:—When the thermometer stands at 212°, and steam escapes from the water, we know it is then able to support a column of mercury 30 inches high; and a column of mercury 30 inches high is equivalent to the pressure of one atmosphere. The steam, then, is of the kind called low-pressure. If, however, the temperature indicated be 250°, then opposite in the table we find 29·4 pounds pressure on the square inch, and 60 inches of mercury; but as 29·4 pounds is double the weight of the atmosphere on the square inch, and also as 60 inches

of mercury is double the height of the column which the air will support, the steam must then be acting with a force equal to two atmospheres.

Mr Tredgold gives the following rule to ascertain the elastic force of the vapour of water, in inches of mercury, at any given temperature of Fahrenheit's thermometer:—To the given temperature 100 is to be added, and the sum divided by 177. The quotient is to be raised to the sixth power, which is the force required. If, for example, the temperature be 307°; to this 100 added gives 407. This, divided by 177, gives 2·3, of which the sixth power is nearly 148, the elasticity of the vapour, in inches of mercury, almost equivalent to five atmospheres. This rule, it is to be observed, only refers to the vapour produced from pure water; when it is mixed with a considerable proportion of saline matter, as in the case of sea-water, a different divisor must be adopted, which is to be regulated by the temperature at which the water boils, for the point of boiling varies with the amount of salt in the water. Water saturated with common salt contains about $\frac{1}{3}\frac{8}{3}$ portions of that matter, and its boiling-point is about 226°. The divisor to be used in this case is 185 instead of 177, and the elastic force of the steam will then be found not to exceed 113 inches.

The following diagram illustrates an apparatus by which steam of different pressures may be raised, and the connection between the temperature indicated by the thermometer T, and the elasticity of the steam in the interior of the copper vessel *bm*, as indicated by the barometer EF, the tube of which dips into a quantity of mercury *m*, placed at the bottom of the copper vessel; *b* is a stop-cock, by closing which the pressure of the steam can be increased as required.

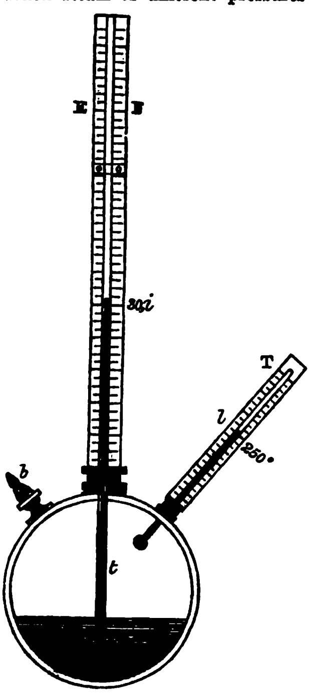

Fig. 1.

Incidental to the formation of steam, it has been observed that there is a great quantity of heat which disappears on the vapour being formed, and which cannot be discovered by the thermometer, but is again given out when the vapour returns to the state of water. The most singular and most important practical fact connected with this property is, that whatever be the temperature at which the water is boiled to form steam, the sum of that temperature, and the number of degrees of latent caloric, is always the same. Suppose the water boils at 212°, and the quantity of latent caloric absorbed be equal to 1000°, the sum of these will be exactly 1212°. But if the water boil at 112° (under diminished pressure), the latent caloric will then be 1100°, to make up the aggregate sum 1212°; and in like manner, if, under increased pressure, the water be made to boil at 312°, the quantity of latent caloric will only be 900°. Hence steam formed at a low pressure, or at the ordinary temperature of the air, does not require a different amount of fuel for its production from that required by steam generated at 100° higher, or any other temperature; for the sum of the latent and sensible heat is always the same—1212°, as measured by the thermometer of Fahrenheit. To convert, accordingly, a given weight of water into steam, the same amount of fuel is required at all temperatures.

Steam is thus seen to have four properties or qualities: its convertibility into water, by which a vacuum can be formed; its expansibility, or property by which a given quantity of steam can increase in bulk, its weight remaining the same; its elasticity, by which it is capable of returning to its original form on the cessation of any force which may act upon it; and, lastly, its latent or concealed heat, in opposition to the sensible heat indicated by the thermometer.

Steam used practically as a moving power is of two kinds—high-pressure and low-pressure. The latter is that used in condensing engines, and varies from 19 to 25 and 30 pounds on the square inch. High-pressure steam varies from 35 to 90 pounds on the square inch. We have now to trace the mechanical effect obtained by the production of steam. Steam, or vapour of water, expands, as we have before stated, into 1728 times the bulk of water; a cubic foot is just 1728 times a cubic inch: hence is derived an easy method of remembering the fact—a *cubic inch* of water converted into vapour gives a *cubic foot* of steam. The temperature being 212°, and the pressure consequently 15 pounds to the square inch, a piston of one square inch in surface, and loaded with 15 pounds, can thus be raised in a tube, which we suppose to be 1728 inches high, by the evaporation of a cubic inch of water placed in the tube below the piston: the number of inches here mentioned gives 144 feet; hence we see that the mechanical effect obtained by the evaporation of a cubic inch of water is equal to the raising of a 15 pound-weight a height of 144 feet; or, to reduce it to the usual way of stating it, 2160 pounds raised one foot high. There are 2240 pounds in a ton; hence is derived the approximative rule, that the evaporation of a cubic inch of water gives a power equal to the raising of a ton one foot high. This effect is found to be the same in all cases, no matter what the pressure is at which the steam may be raised. We have already shewn that the bulk or volume of steam depends upon the pressure; thus, steam at a pressure of 45 pounds to the square inch will occupy a space of 610 cubic inches, and would, in the case above stated, only raise the piston and weight one-third of the distance, or 48 feet; but this multiplied by the pressure will give the same result as 15 multiplied by 144.

In the condensing or low-pressure engine, as it is usually called, the mechanical effect produced by the condensation of any given quantity of steam is obviously equal to the evaporation of the same quantity of water into steam. Thus, a vessel of one cubic foot in capacity—when the piston with which it is furnished is raised to its full height—is filled with steam raised from a cubic inch of water. On the condensation of this steam, and its conversion into water, the piston will descend in the vessel pressed down with a pressure of 15 pounds to the square inch—which obviously exerts a power capable of lifting a certain amount through the aid of chains and pulleys.

From this theoretical estimate of the mechanical effect of steam, a considerable proportion must be taken for the loss by friction and other causes.

The mechanical effect obtained by the expansion of steam remains to be stated. The pressure of a gaseous fluid compressed or forced into any vessel varies with the amount of compression—where its natural bulk is compressed into half the space, the pressure is doubled; and so on. The converse of this applies where the gaseous fluid is allowed to expand itself into greater bulk. Where the space it occupies is twice its usual amount, the pressure it exerts is only half; if expanded

into three times its usual bulk, its pressure is decreased to one-third; and so on. Steam, in common with other gaseous fluids, follows this law. By cutting off the entrance of the steam into any vessel or cylinder in which a piston moves, at a point equal to half the stroke or length of the vessel, the piston is propelled through the remaining portion of the cylinder with a force gradually decreasing in proportion as the steam expands. At the end of its stroke, the steam, which originally filled one-half of the cylinder, and exerting say a force of 30 pounds on the square inch of piston, will have expanded so as to fill the whole of it; but the pressure will only be *one-half* of what it was originally. In this case, it is evident that a quantity of steam equal to half the space of cylinder has been saved; and that although the pressure exerted by the remaining half decreases as it expands, still the power it *does give out* is obtained for nothing—that is, without the expenditure of a further supply of steam. By saving steam, fuel is saved; and although the power of the engine is diminished, still in practice the saving of the fuel is greater in proportion than the diminution of the power. Hence the economical value of the expansive system of working.

This mode of using the steam expansively may be illustrated in the following manner:—If the piston is pressed by a weight of one ton, and can be raised four feet when the cylinder is supplied with steam of the ordinary pressure of one atmosphere, the same piston loaded with four tons will be raised one foot, if the cylinder be one-fourth full of steam of four atmospheres. When the steam of four atmospheres is admitted, it is cut off when the piston is raised one foot. But the piston has now received an impulse, and the steam beginning to expand under it with a gradually diminishing force, it is raised to the second foot, so that the volume of the gas is doubled, and its elasticity becomes only equal to two atmospheres. On the piston being elevated to the third foot, the volume of the steam will be trebled, and its pressure or elasticity now reduced to one atmosphere and a third. But when the piston is raised the fourth foot, the steam will have been quadrupled in volume, and the force equal to that of one atmosphere.

This principle is now much employed, and particularly in the Cornish mines, where it has been used with great success, the pressure of the steam in the pumping or drainage engines being four atmospheres. The benefit of working a steam-engine in this mode increases the earlier the steam is cut off, but not much after it is rarefied four times.

Steam cut off.	Power multiplied.
$\frac{1}{2}$	1·7
$\frac{1}{3}$	2·1
$\frac{1}{4}$	2·4
$\frac{1}{5}$	2·6
$\frac{1}{6}$	2·8
$\frac{1}{7}$	3·0
$\frac{1}{8}$	3·2

We now come to consider the relative qualities of different fuels, and the economical effects produced by their combustion. The mechanical effect produced by the combustion of a given quantity of fuel varies much according to its evaporative properties, and the arrangement and construction of the boilers and furnaces in connection with which it may be used. In ordinary cases, the quantity of water converted into steam is six or eight pounds for each pound of coal consumed. Where a cubic foot of water is converted into steam per hour, a mechanical effect equal to an estimated horse-power is obtained; to evaporate this quantity, a weight of six pounds of coal on an average of qualities is required. Hence is deduced the approximative rule, that by the combustion of six pounds of coal per hour, a mechanical effect of one horse-power is obtained. By a high degree of care taken in the construction and management of boilers and steam-engines, a much higher value can be given to fuel. In some of the Cornish engines, three pounds of coal, and in some cases 1¾ pounds, give a horse-power.

In carrying out the evaporation of water in steam-boilers, the great point to be attended to is to produce the greatest amount of heat from the smallest quantity of fuel. Charcoal, or the substance carbon, is, properly speaking, the principal ingredient in the combustible matters which are usually taken to produce heat. It constitutes the main bulk of coal, of coke, of anthracite, which is a species of natural coke, and of wood in all its varieties.

During the process of combustion, the quantity of heat which is disengaged can be precisely determined; as, for instance, by ascertaining how much of a given amount of combustible matter is required to raise the temperature of water from 32° to the boiling-point (212°).

It is here to be carefully noted, that to raise water to the boiling-point, and to convert water into steam, do not imply the same thing, though they both imply the application of heat steadily to the fluid matter. This arises from the great quantity of latent caloric which the steam requires, and which amounts, by calculation, as well as by careful experiment, nearly to 1000° of Fahrenheit; that is to say, if it takes a given time, with an equal and uniform quantity of heat, to raise water from 32° to 212° (180°), it will require that time multiplied by $5\frac{5}{9}$ to convert the water into steam. But in one period—namely, the time required to raise the water to the boiling-point—as much heat as raised the water 180° was added, and 180° multiplied by $5\frac{5}{9}$ gives exactly 1000°. It is to supply this great quantity of latent caloric that so immense an amount of coal is consumed by the steam-engine. For if one pound of the best coal raises 33·3 pounds of water from 32° to 212°, then one pound will only suffice to convert 5·5 pounds of water into steam. Or, while one pound of coal raises 33·3 pounds of water to the boiling-point, it will require about 5½ pounds more of the same kind of fuel to convert all that water into steam.

To convert the coal into those chemical compounds, during which the evolution of heat takes place, a very great proportion of air is required; for the atmospheric air contains four-fifths of its bulk of matter, which does not in any manner assist combustion. Two and a half pounds of oxygen, or nearly 30 cubic feet, are requisite for the combustion of one pound of coal; 150 cubic feet, therefore, of atmospheric air will supply this. It has, however, been found that one-third of the air which enters the furnace passes through it without directly contributing to the process of combustion, but withdraws heat; the actual amount, therefore, of air required is in round numbers about 220 cubic feet.

The results of experiments on bituminous coal go far to prove the correctness of the opinion that has long been held, that its evaporative value is equal to the evaporative value of coke produced from it. Indeed, it has been found that the work produced from coke is actually greater than that of the coal from which the coke was made. Government some time ago instituted a series of experiments in order to test the relative values of a variety of coals useful for the purposes of the steam-navy. The results were published in an elaborate report by Dr Lyon Playfair and Sir H. De la Beche, which contains a vast amount of practical information on fuel fitted for combustion in steam-engine furnaces. In this report, a table is given shewing the high economical value of coke, as compared with the bituminous coal from which it is produced. Thus, when the quantity of water evaporated by one variety of bituminous coal was 9·35 pounds, the coke from this evaporated 11·301; another quality, evaporating 9·46, gave in the shape of coke 12·554; and so on of certain qualities as now stated. Thus, one coal gave 8·86 as its economic evaporating power; its coke, 10·873: another coal, 7·47; its coke,

8·144: another quality, 8·94; its coke, 10·601. In a table given by Tredgold in his work on *Warming and Ventilating*, the superiority of coke over coal is also shewn; thus, to evaporate one cubic foot of water into steam, takes 8·4 pounds of Newcastle coal, while 7·7 pounds of coke do the same work. Should further trials bear out this economic value of coke, it will have an important bearing on the manufacture of gas, which, instead of wasting the coal from which the gas is extracted, will actually render it more valuable than before. Coke might also be made separately with profit, by saving the other products of the distillation.

Before proceeding to the practical details of the steam-engine in its various forms, we think it well to give a few historical notes, shewing the rise and progress of the invention.

It appears, by careful examination of the records of history, that the action of steam for producing motion (though not then proposed to be applied to practical purposes) was known as early as 130 years B.C. This was produced by an instrument denominated an *æolipyle*, described by Hero of Alexandria, of which a figure is annexed, and which may be considered the original of the steam-engine. The æolipyle is formed by a globular metallic vessel, which rests on pivots, at and where it can revolve with perfect facility. Two tubes proceed from this ball at right angles to the pivots, shut at the extremities, but with a small aperture at the side, whence steam may escape. The pivots are the extremities of tubes connected with a boiler below, as marked in the sketch. On the boiler being heated, steam passes by the pivot tubes, C, B, into the cylinder, from which it issues by the little aperture F at the side of the cylinder tube E. As the steam escapes, it rushes out with great force; and as it presses on the side opposite to the aperture, it forces it and the cylinder to move round in the contrary direction. One tube will suffice.

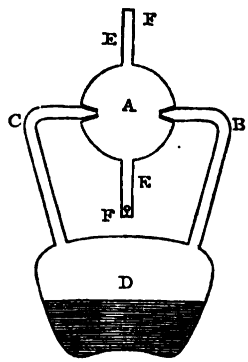

Fig. 2.

The next notice of steam-power worthy of our attention is in the seventeenth century. In the year 1663, a work was published by the Marquis of Worcester, named, in the language of that period, *A Century of the Names and Scantlings of such Inventions as at present I can call to mind to have Tried and Perfected.* The following extract, describing what he terms a 'fire waterwork,' seems distinctly to convey the idea of a steam-engine:—'An admirable and most forcible way is to drive up water by fire, not by drawing or sucking it upwards, for that must be as the philosopher calleth it, *intra sphæram activitatis*, which is best at such a distance. But this way *hath no bounder* if the vessel be strong enough; for I have taken a piece of a whole cannon, whereof the end was burst, and filled it three-quarters full of water, stopping and screwing up the broken end, as also the touch-hole, and making a constant fire under it; within twenty-four hours it burst, and made a great crack; so that, having a way to make my vessels so that they are strengthened by the force within them, and the one to fill after the other, I have seen the water run like a constant fountain stream forty feet high; one vessel of water, rarefied by fire, driveth up forty of cold water. And a man that tends the work is but to turn two cocks, that one vessel of water being consumed, another begins to force and refill with cold water; and so successively—the fire being tended and kept constant, which the self-same person may likewise abundantly perform in the interim between the necessity of turning the said cocks.'

In 1698, Mr, or Captain Savery, obtained a patent for a steam-engine, which was the first introduced to raise water. The principle of his plan consisted in injecting steam into a vessel connected with a vertical pipe, dipping into the water to be raised, and then condensing it by cold water, so as to form a vacuum, or, at all events, a space in which there is vapour of very feeble elastic force. By the pressure of the atmosphere, the water was then driven up until it attained a height proportionate to the pressure of the atmosphere, diminished by the force of the uncondensed vapour. By a peculiar but simple disposition of the valves, the return of the water was prevented; but as the water could not in this manner be elevated higher than twenty-six feet (sixty-four feet by force of steam), the plan was not adopted to any extent.

The next step in the improvement of the steam-engine which we have to record, is the introduction of the cylinder and piston. In the former attempts above noticed, the steam acted upon water; here, upon a solid piston moving in a cylinder. To Papin, a celebrated Frenchman, the inventor of the safety-valve and steam-digester, is due the suggestion of this great improvement. His plan was, however, very crude, and obviously incapable of practical use, inasmuch as the cylinder itself contained the water which produced the steam, which being raised, elevated the piston; the fire was then removed, and the cylinder cooling, the steam was condensed, and the piston fell. This was merely a toy, but it contained the germ of the principle which, in other hands, made the steam-engine ultimately the grand prime mover which we see it now is. In the next step which we have to record, this cylinder and piston will be seen as an important part of the mechanism. In the atmospheric engine invented by Newcomen and Cawley in the year 1713, these very important improvements may be traced—the cylinder and piston—the separate boiler—and the beam by which the mechanical force obtained was made effectual in pumping water from coal-mines; at that period the great end for which steam-power was so desiderated. The boiler B, fig. 3, is placed over a furnace; from this, a tube conveys the steam to the cylinder C, immediately connected with the boiler, the supply of steam being regulated by the valve V.

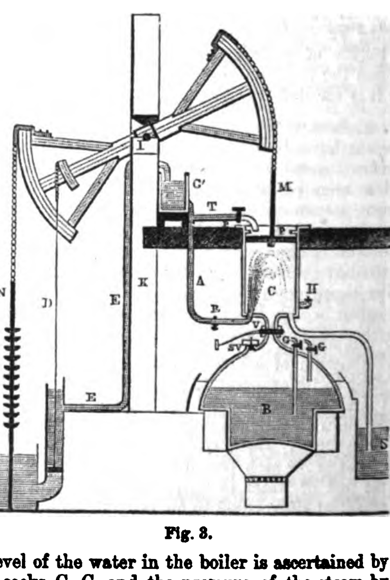

Fig. 3.

The level of the water in the boiler is ascertained by the gauge-cocks G, G, and the pressure of the steam by the safety-valve SV—these will afterwards be described. The piston P works in the cylinder C, and is kept tight

by a stream of water issuing through a pipe regulated by a stop-cock T, and supplied from a cistern C'. From the same cistern the water for condensing is supplied to the cylinder by the pipe A; the water of condensation is led from the interior of the cylinder by a pipe to a cistern S, this being placed at a considerable distance below the cylinder, in order to balance the atmospheric pressure, which would otherwise force the water up the pipe into the vacuum created in the cylinder. The air which gains access to the cylinder by the steam, is allowed to pass off through the snifting-valve H, which opens upwards. The piston-rod, M, is connected by a chain to a quadrant placed at the end of a beam, which vibrates on a centre I; the pump-rod, N, is attached in a similar manner to the other end of the beam. A second and smaller pump supplies the cistern C', through the pipe EE. The operation of the engine is as follows:—The fire being properly raised, and steam freely formed, the valve, V, is opened, to allow the entrance of the steam. The snifting-valve, H, is now forced open, and the air escapes along with the steam, until the cylinder is full of steam. The regulator-valve, V, is now shut, and the stop-cock R, on the pipe A, being opened, the cold water is injected, and condenses the steam. But as a vacuum is effected by the condensation of the steam, the pressure of the air, acting with a force equal to fifteen pounds on the square inch on the surface of the piston, carries it down to the bottom of the cylinder, and consequently raises the other end of the beam to which the pump-rod, N, is attached. In this manner the water is raised from the mine; and, by a repetition of the movements already noticed, a constant discharge of water results.

The celebrated engineer Smeaton brought this form of engine to a high degree of perfection; and Beighton of Newcastle rendered it self-acting, by introducing what is called hand-gear, by which the engine opened and closed the various valves. This was an improvement on an assemblage of strings and levers, which were introduced, it is said, by a boy named Humphrey Potter, to avoid the trouble of a personal superintendence.

Great as was the advance effected by this form of engine, it had many defects, the chief of which we now enumerate. Much steam was lost during the process of the heating of the cylinder after each condensation; for it had always at least to be raised to the temperature of the steam before the steam could, as such, continue in it, and be in any degree efficient; and, on the other hand, the cold air which followed the descent of the piston, necessarily withdrew a considerable portion of heat. By the calculations of Watt, it was estimated that *three* times as much steam was expended in this manner as would have been equal to work the engine—a loss, therefore, equal to 75 per cent. Nevertheless, this, as has been correctly observed, 'was the first really efficient steam-engine—that is, the first engine which could be applied *profitably* and *safely* to the most important purposes for which such machines were required at the time of its invention.'

The happy conception which formed the first step in the career which has immortalised the name of Watt, was that of *condensing the steam without cooling the cylinder*. After the notion of separate condensation had occurred to him, all the other details of the engine were of comparatively easy introduction. His first improvement constituted what has been termed the single-acting engine. In this form of the engine the steam was admitted only above the piston at first, the vacuum being below it. When the piston had gained the lower part of the cylinder, the communications between the steam-pipe and cylinder, and also between the condenser and cylinder, were closed; and through the medium of a tube communicating laterally, the steam which was above, diffused itself below the piston, so that on either side it was subject to an equal force. But on the other extremity of the beam there was a weight, which raised the piston up, and the steam all necessarily flowed below the piston. On the communication between the condenser and cylinder being made free, a vacuum was induced, and the steam-pipe being then opened, a rush or current of steam proceeded to the upper part of the piston, and the movements were repeated as before.

This form of engine was not by any means well suited for the purposes of communicating motion to machinery, in consequence of the inequality of its action; but it served admirably for the purpose to which it had been first applied—namely, that of raising water from mines. It is, however, in a great measure, even for that latter purpose, superseded by the double-acting engine of Watt, which we shall hereafter describe.

We now proceed to the consideration of the various parts of the modern steam-engine in its different varieties; and first as to the boiler and its appendages.

The form of boiler introduced by Watt was termed the 'wagon.' Fig. 4 shews a transverse section of this: *a* the fire-bars and ash-pit, *d* the boiler, *bb* the furnace, *c*, *c* the flues. The boiler is sometimes strengthened by stays *e*. Fig. 5 is a longitudinal section of the wagon-boiler with its appendages as arranged by Watt. These we shall hereafter

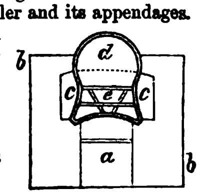

Fig. 4.

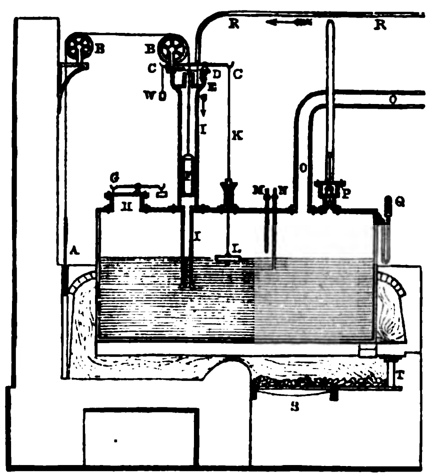

Fig. 5.

describe in detail. The wagon-boiler is now rarely used, our best authorities condemning it as unsafe, and by no means economical. The Cornish or cylindrical fluid-boiler is much used, and is considered to be safe and very economical in its operation. To admit of the system of alternate firing (see CONSUMPTION OF SMOKE, No. 31), two flues are used, as in fig. 6.—the fire-bars are situated in these flues. Fig. 7 is a longitudinal section of this

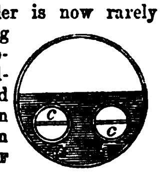

Fig. 6.

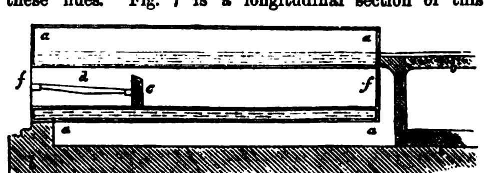

Fig. 7.

form; *aa* is the boiler, on a brick foundation *bb*; *c* the

fire-bridge, *d* the fire-bars, *f* the internal flue surrounded by water. Fig. 8 is a plan shewing the two

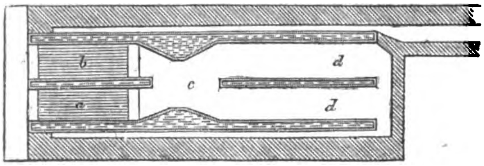

Fig. 8.

fireplaces *a*, *b*, with the mixing chamber *c*, and the two flues *d*, *d*.

The multitubular boiler, shewn in fig. 9, is one which is rapidly coming into extended use. The boiler rests on brick supports *e*, *e*, *e*; *a*, *a* the fire-bars; *b* the fire-bridge; *d* a valve for admitting air to an air-distributer *c*, passing the air to the back of the bridge, to promote combustion of the smoke. The heated air passes through a number of tubes *n*, *n*, surrounded by water, and ultimately passes off to the chimney through the smoke-box *oo*. *vv* the safety-valve, *h* the man-hole door to gain access to the interior for cleaning purposes, &c., *f* a pipe for carrying off the water and deposits, *tt* the stop-valve in the pipe leading to the engine, *x'x* the water-feed apparatus—these we shall describe hereafter. Having given the principal varieties of boilers now in use, we proceed to illustrate the appendages.

And first as to the supply of water. In Watt's boiler

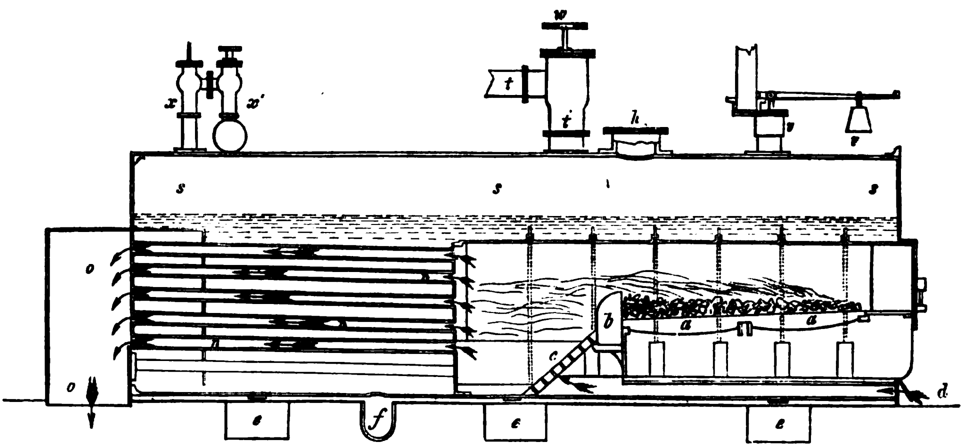

Fig. 9.

(fig. 5), the apparatus to secure this was as follows:—The cistern DE is supplied with water from the hot well of the engine. A valve is situated at the bottom of the cistern, which is made to open upwards, on the rod being raised which connects it with a lever D. This lever is so placed as to move on a fixed point at the upper part of the cistern. At one extremity of it, a small wire, K, is attached, running through a steam-tight aperture in the boiler, having a float, L, at its termination resting on the water. To counterpoise this, there is a weight, W, suspended at the other extremity of the lever connected with the cistern. As this float is balanced in the water, when it is rapidly evaporated, it will follow the water-level, and as it descends, will necessarily bring down the arm of the lever to which it was connected; the other arm will be elevated in a corresponding manner. But the valve in the feed-pipe being attached to a rod which is fixed to the lever, will be carried upwards as it is raised, and the water will pass down, until the float, being raised in a corresponding degree, will enable the other arm of the lever to which the counterpoise was attached to fall, and thereby bring down the other end of the lever, and close the valve. By this arrangement, as long as there is a sufficient supply of water from which the cistern can be filled, there will always be a sufficiency running down in a continuous stream to feed the boiler for the production of steam.

In consequence of the general adoption of the principle of expansive working of condensing steam-engines, this method of supply is now being superseded by the plan of forcing the water directly into the boiler by means of a force-pump. In connection with this, an apparatus known as the 'differential feed' is frequently used. This is illustrated in fig. 10. A pipe, *a*, is carried down within a few inches of the bottom of the boiler, *bb* is a circular chamber into which the water is forced by the pump. There are two apertures in this chamber, each supplied with a valve, as *c*, *d*, these opening upward.

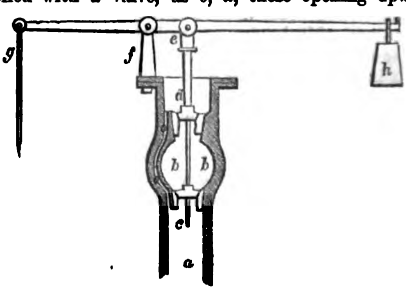

Fig. 10.

The chamber *d* communicates with the pipe *a*, and with the boiler by means of a channel or way, *oo*, in the thickness of the pipe. A lever oscillates on a standard *f*; and is connected with the valve-spindle by a rod *e*. A rod, *g*, is connected with the stone-float in the interior of the boiler (see L, fig. 5), counterpoised by a weight *h*. On the float falling, it pulls down *g*, raises *h* and the valves out of their seat; water is allowed then to pass down *c* into *a*, and from thence to the boiler. As the pressure of the steam, on the surface of the water in the boiler, might force water up the pipe *a*, and open the valve *c*, and thus allow water to pass down without any influence of the float, the small channel *oo* prevents this action. The water forced up the pipe *a* by the pressure of the steam, passes through *oo* into the chamber *d*; and pressing on the top of the valve *d* with as much force as it presses on the under side of *c*, the pressure is thus equalised. This form of feed is also applied to high-pressure boilers.

The height at which the water in the boiler stands is ascertained by two methods—the gauge-cocks and the water-gauge. The former contrivance is illustrated in fig. 5 at M, N. One pipe, N, is made long enough to reach the level at which water should be at all times, below which it should never fall. The shorter pipe, M, is taken down to the level at which steam should always be, and to which the water should never rise. Consequently one pipe, when its stop-cock is opened, should always pass steam, the other water. When N passes steam, there is too little water in the boiler; when M passes water, there is too much. The attendant adjusts the supply accordingly. The water-gauge, illustrated by fig. 11, affords an evidence of the level of the water in the boiler by inspection: *aa* is part of the front of the boiler, *bb* the level of the water; a pipe, *gd*, communicates with the steam-space of the boiler, the pipe *e* with the water-space; a glass tube, *c*, connects these two, and stop-cocks, *g* and *f*, are placed so as to cut off the connection when required. If both cocks are opened, the level of the water in *c* shews that in the boiler—the pressure in *c* being obviously the same as in the boiler. A small stop-cock placed at the lower part of the pipe *c*, allows the water which is in it to pass off, leaving the pipe empty when required. A great variety of apparatus for effecting a safe supply of water to boilers has been introduced, and many ingenious appliances to warn the attendant engineer of a deficient supply—one of the great causes of boiler-explosions.

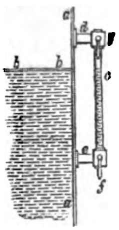

Fig. 11.

The next appliance we have to notice is the important one of the safety-valve; the duty of which is to admit of the steam's escape when it exceeds a certain pressure, and to prevent it until the pressure necessary to work the engine is obtained. An improved arrangement of valve is shewn in fig. 12: *aa* is a steam dome fixed on

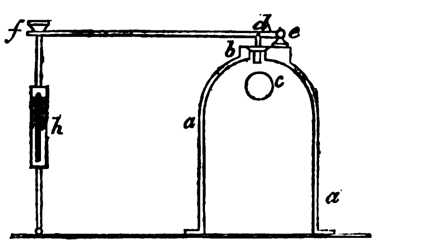

Fig. 12.

the top of the boiler, a conical brass valve, *b*, is placed in the seat steam tight; this valve is connected with a lever *df*, by a lever *d*, this being jointed to a stud *e*, fixed to the dome. The other end of the lever is pulled down by means of a spring *h*, attached to the boiler. The pressure of the spring is adjusted as desired by the nut *f*. The index of the spring shews at a glance the pressure of steam in the boiler; thus, if the nut is screwed down, depressing the end of the lever until the index points to, say 45, on the steam lifting the valve, its pressure is known to exceed 45 pounds. In the generality of cases, instead of a spring, a weight is used; this is moved along the lever according as the pressure is required, the lever being graduated. The further the weight is from the stud *e* (fig. 12), the greater the pressure. As the weight is apt to be tampered with by attendants, thus increasing or otherwise altering the pressure considered to be safe, Mr Fairbairn has introduced a plan of safety-valve, in which the weight is in the interior of the boiler, all that is visible being a small dome. The great objection to the form of conical safety-valve is the likelihood of the valve jamming or sticking in its seat. Mr Nasmyth obviates this difficulty by carrying the valve-spindle into the interior of the boiler, and loading it there with the necessary weight. To the lower part of the spindle he attaches a sheet-iron appendage, which, being acted upon by the ebullition of the water, sways to and fro continually, and, by the intervention of the spindle, keeps the valve moving in its seat, but not to such an extent as to allow of any escape of steam. The form of valve is spherical, which admits of less friction than the conical.

Although the safety-valve regulates the extent to which the pressure of the steam may go, it does not indicate the amount or degree. To do this, the apparatus termed the steam or mercurial gauge is used.

This is an iron tube B (fig. 13), bent in the shape of a U, the upper end of which, at A, is of glass, furnished with a graduated scale. Mercury is poured into the tube, and stands at the same level in both legs when the steam is not admitted to the short leg. On this being the case, the pressure makes the mercury rise in the long leg proportionate to the pressure. For each inch the mercury rises in the long leg, a pound of pressure in the boiler is indicated; but as the tube is double, an inch in the long leg is actually two inches of rise of the mercury.

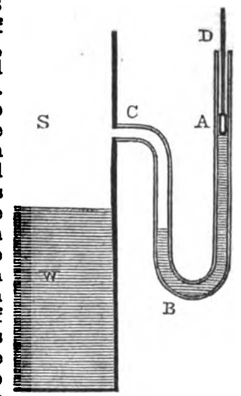

Fig. 13.

Gauges for high-pressure boilers are also used; they are generally in cases, with graduated faces.

In Watt's boiler the draught of the furnace was regulated by a float F, placed in the tube of the 'feed.' The pressure of the steam in the boiler forced the water up the tube, and with it the float F, the damper A, connected with the throat of the flue, and attached to the float by the chain passing over the pulleys R, R, also fell, and closing up the throat of the chimney, lessened the draught, and reduced the pressure of the steam. Self-acting dampers have not been very generally introduced into modern practice, the dampers being more frequently regulated by hand; a counterpoise weight, connected with the damper by chains passing over pulleys, being placed within the reach of the stoker.

The singular phenomena attendant upon the explosion of boilers have given rise to numerous theories to account for them. It is a subject still a source of much discussion amongst engineers and scientific men. It is pretty generally conceded that if all the appliances we have indicated are properly fitted up and managed, the chances of boiler-explosion will be materially lessened. The two great points, according to the eminent authority Mr Fairbairn, being the supply of water and good safety-valves, the former being, if possible, more important than the latter, especial care should be taken never to allow the flues or parts of boiler which are exposed to the action of the fire to become bare; the water should in all cases cover them. Another safety contrivance we have yet to notice is the fusible plate. This is a plate composed of a combination of metals, tin, lead, and bismuth, which melt at a temperature ranging between 280° to 750°. This plate is fixed in the upper part of the boiler, and protected from its *pressure* while exposed to its temperature. If this greatly increases, from any cause, the metal melts, and leaves an opening for the escape of the steam. From the metal melting unequally, a source of danger rather than of safety has been supposed by some to lie in this contrivance. Such an authority as Mr Fairbairn, who has the following, will surely be of some weight on the opposite side of the

question. 'In France,' says Mr Fairbairn, 'the greatest importance is attached to those fusible plates..... In this country, these alloys are not generally in use; but in this respect I think we are wrong, as boiler-explosions are not so frequent in France as in this country; and high-pressure steam, from its superior economy, is more extensively used in France than in England.' Many engineers adopt the precaution of having a hole in the lower part of the boiler, below the water-level. This is filled up tight with a plug of lead: so long as this is covered with water, the heat of the furnace does not melt it; but on becoming exposed by the evaporation of the water from want of attention to the supply, it melts, and allows the steam and water to rush out into the furnace and flues.

Steam-engines, as used in modern practice, are divided into two classes, those in which the cylinder is fixed, and those in which it is movable—that is, in which it oscillates: this latter variety, called the oscillating engine, is a very important one, and has especial bearing on marine-engine construction.

The fixed-cylinder engines, as well as the oscillating ones, are again divided into two grand classes or divisions—those in which the steam is condensed after leaving the cylinder, commonly called low-pressure, and those in which the steam, after working the piston, passes to the atmosphere, called high-pressure. The exigencies of modern practice have tended to alter this distinction of low-pressure and high-pressure engines very materially. In former times, a condensing engine always worked with low-pressure steam, now they more frequently work with steam of high-pressure than with low, since in the great majority of well-managed engines the expansive principle is put in practice. Not far from where we write, a pair of condensing-engines are working with a pressure of steam at the boiler of 75 pounds to the inch. Hence the terms condensing and non-condensing more accurately define the two classes.

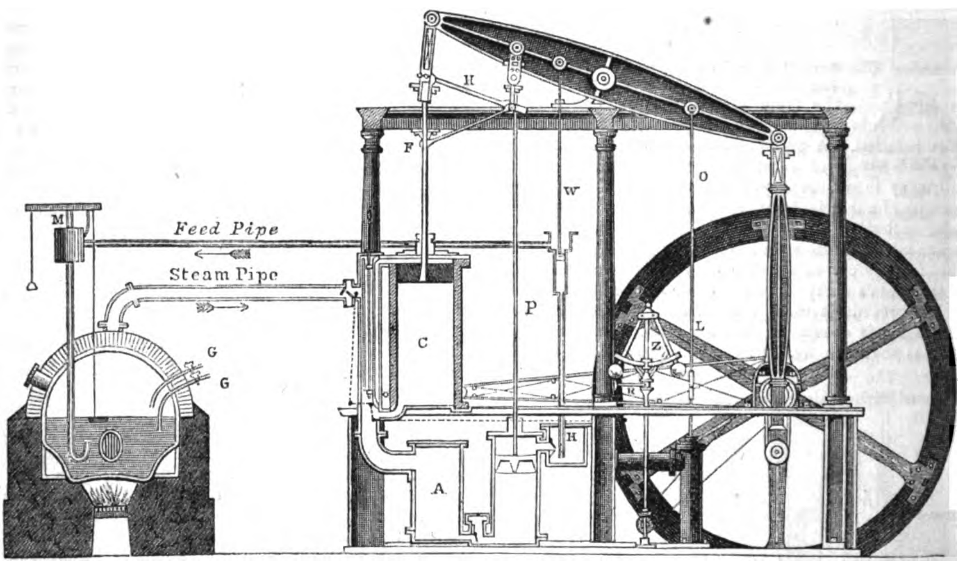

Fig. 14.

The form of engine illustrated in fig. 14 is that of Watt's double-acting engine, of which the following is a general description. The steam from the boiler passes along the steam-pipe to the valve-casing, from whence it is 'distributed,' as it is termed, to the upper and under sides of the piston, producing its alternate up-and-down motion in the cylinder C. After working the piston, the steam passes to the condenser A, where it is condensed by coming in contact with a jet of cold water—omitted to be shewn in the diagram. From the condenser, the water of condensation, together with the air which obtains admission through the steam, and which, if allowed to accumulate, would ultimately prevent the engine working, is drawn off by the air-pump, and delivered to the hot-well H. An arrangement of valves prevents the water from returning to the air-pump from the cistern, and also prevents the water in the air-pump which may remain therein at the bottom from being again forced into the condenser on the down-stroke of the air-pump piston. The condenser and air-pump are placed in a cistern filled with cold water, supplied by the pump OL. The injection-water to the condenser is supplied from the cistern, and is regulated by a stop-valve. The piston-rod is connected with the end of the working or walking beam, and is kept parallel by a beautiful arrangement of levers termed the parallel motion. The other end of the beam is connected to the upper end of the connecting-rod, which at its lower end is attached to the crank. To equalise the motion, a heavy wheel, the fly-wheel, is keyed on to the crank-shaft. In the revolution of the crank there are two points, called the dead-points, at both of which the power of the engine has no effect in causing any revolution. These points obtain, when the piston is at the termination of the up-and-down stroke; at the former, the only effect of the engine is by means of the connecting-rod to press down the crank; while at the latter the effect is to pull it out of its bearings. By the momentum acquired by the fly-wheel while receiving the full power of the engine, the crank is carried past its dead-points. Where the engine is required to act with great uniformity, the irregular action of the engine even with a fly-wheel is much felt, and various contrivances have been adopted to equalise the motion; these we have not space to describe. Having now given a general idea of the arrangements of the engine, we proceed to describe the parts and movements in detail.

The Cylinder and the distribution of the steam to it

by means of valves, termed slide-valves.—These are of three varieties—the long D, the short D, and the three-ported. There are other forms of valves, as the equilibrium, puppet valves, &c., but the slide-valve is the form generally used. We shall describe the long D valve generally adopted in condensing engines, as illustrated by fig. 14. Fig. 15 is a diagram illustrative of the position of the valve when the piston, *d*, is at the bottom of its stroke.* The valve is in the form of half a tube with flat portions *a*, *a* (fig. 16), made very smooth, and which work steam-tight in the face of the cylinder; the back, *bb*, is hollow; and stuffing is applied at top and bottom, which works against the back of the valve-casing; by this means the valve works steam-tight in the casing. The steam which fills the space of the cylinder above the piston is escaping through the upper steam-port *f*, down the hollow *bb*, at the back of the valve, and thence to the condenser by the pipe *h*. The steam gains admission to the hollow space in front of the valve through the throttle-valve *g*; the steam from the boiler gaining admission to this space—and is seen passing downwards through the lower steam-port *e*, to the under side of the piston, which it forces to the top of the cylinder; during its upward motion, the valve is moved into the position shewn in fig. 17. The steam below the piston is now passing to the condenser by the lower steam-port, which is left uncovered; and the steam is passing to the upper steam-port *c*. The valve is moved by the rod *b'*, which is connected with the eccentric rod as shewn by fig. 18. In

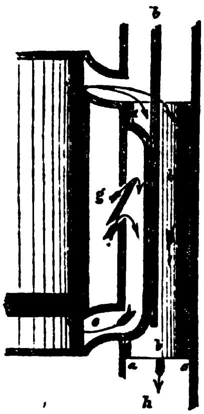

Fig. 15.

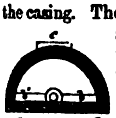

Fig. 16.

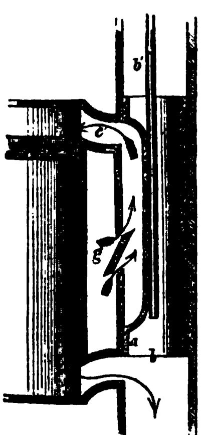

Fig. 17.

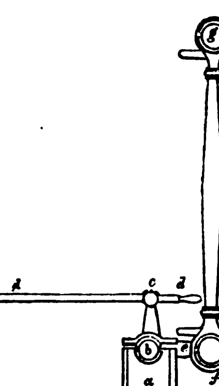

Fig. 18.

the number on MECHANICS, we have explained the action of the *eccentric*, and shewn how the circular motion is changed into any required amount of rectilineal motion. In fig. 18, *dd* is the eccentric rod, which gives a to-and-fro motion of the lever *cb*, which works in the plummet-block *a* (see MECHANICS). The other end of the bell-crank lever, *e*, is jointed to the end, *f*, of a side-lever, the upper

* The length of the stroke of an engine implies the space moved through by the piston in its ascent or descent, and consequently, during one complete revolution of the crank-shaft, the piston moves through twice the length of the stroke.

end of which is jointed to the extremity of the valve rod cross-head. A similar arrangement of levers, as in fig. 18, is at the other side of the engine; the shaft of the bell-crank lever, *be*, reaching across the breadth of the engine. This shaft is termed the rocking-shaft or weigh-shaft. By this arrangement, the eccentric causes the cross-head of the valve-rod to work up and down; and by this means the valve which is attached to the centre of the cross-head by the rod *b* (fig. 17), is moved in the valve-casing as required.

The Piston.—The old method in use for keeping the piston steam-tight was the wrapping of hemp tightly round it, a space being left between the upper and lower disks into which the hemp was placed. This plan is now rarely adopted, metallic pistons being almost universally used. Fig. 19 illustrates a form used; *b*, *b* are two rings of metal cut into segments; these are pressed outward by means of a spring *c*; *aa* the part into which the piston-rod is fixed. A simple metallic piston is made by having two rings of metal, out of which a part is cut; the two rings are placed one above another, the cut part of the one opposite to the solid part of the other. The two rings are placed between two disks the same diameter as the inside of cylinder, and compressed so as to bring the edges of the cut together; in this state, they are put into the cylinder; and the tendency of the rings to expand and to widen the distance between the cut edges, keeps them always pressed against the interior of the cylinder.

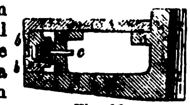

Fig. 19.

The Cylinder-cover Stuffing-box.—The piston-rod, *bb*

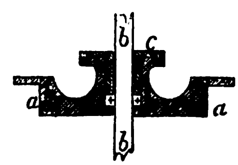

Fig. 20.

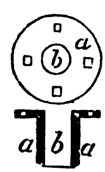

Fig. 21.

(fig. 20), works steam-tight in the aperture in the cylinder-cover, by what is called a stuffing-box. An annular space is left in the cover, and into this a gland, *aa* (fig. 21), is placed; the size of the aperture, *b*, in this is as near as possible equal to the diameter of piston-rod *bb*. A packing of hemp is forced into the parts marked * * in fig. 20; and the gland pressing on this, keeps it tight up to the piston-rod. The gland is secured to the cylinder-cover by means of bolts and nuts.

The Parallel Motion.—In the atmospheric engine of Newcomen, and the single-acting engine of Watt, the piston-rod was connected with the working-beam by means of a chain; the piston pulling the end of the beam down, and the counterpoise on the beam pulling the piston up. When, however, the steam-engine was applied to the production of circular motion, the piston-rod had to act upon the beam by pushing as well as pulling, the chain was therefore no longer eligible. As the end of the beam described part of a circle, and the piston-rod a right line, it was necessary, in making the connection between them, to arrange so as to maintain the parallelism of the piston-rod. This Watt effected by means of his parallel motion, which the reader will find illustrated in the number on MECHANICS.

The Governor and Throttle-valve.—The supply of steam to the cylinder is regulated by a valve called the throttle-valve. This is a disk of metal fitted to the interior of the steam-pipe, and moving on a horizontal axis. The edges of this plate are made angular, so as to fit steam-tight against the pipe when closed, its position being at an angle to the length of the pipe. When the valve is horizontal, the full supply of steam is admitted; as its position approaches the vertical, the supply is correspondingly lessened. In some small engines, this valve is

operated upon by hand; but in the majority, the engine affects it according to its own necessities. The mechanism so long used in water-mills, known as the governor, was applied by Watt for this purpose. The nature of this piece of mechanism will be understood by the following fig. A spindle or upright rod, with a pulley on its lower

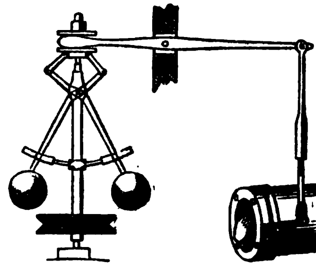

Fig. 22.

part by which it is moved, receiving motion through a strap attached to the shaft or axle, has two balls, which revolve along with it. These balls, by the centrifugal force generated by the revolution of the spindle, fly out from, or approach to the spindle according to the rate of revolution; the balls being attached to jointed levers moving in a curved guide fixed to the spindle. The levers act upon a movable boss, which is embraced by a forked lever acting upon the handle of the throttle-valve. As the speed of the engine increases, and the rotation of the governor becomes more rapid, the balls fly outwards, and extending the lower levers, raise the boss, and depresses the end of the lever of the throttle-valve. This being closed more or less, the quantity of steam admitted to the cylinder is diminished; the speed of the engine is lessened; the governor rotates less rapidly; the balls approach the spindle, pulling down the boss, and raising the lever of the throttle-valve, and admitting more steam to the cylinder. These changes are continually going on while the engine is in operation.

This apparatus is only comparatively efficient, the great drawbacks attendant upon its use being—first, the time which elapses before the governor can act upon the throttle-valve—the levers taking time to assume their relative position; secondly, the rapidity with which the valve can be opened to 'full,' or closed to 'shut,' there being too little gradation between these two points. Various contrivances have therefore been brought out, which have for their aim, that nice and immediate regulation of the valve, so necessary to bring about the regularity of action and the freedom from oscillation in the working of the engine desiderated for many processes in the arts and manufactures. From the want of immediate control over the valve, engines often run away, as it is termed, breaking many of the parts, and doing much damage; the immediate cause generally being the sudden throwing off of the work of the engine, as the stoppage of a number of looms, &c., by the breaking of a shaft. A form of throttle-valve or steam-valve has been recently introduced, and found very effective; there are two valves of the same form and species as the conical safety-valve—these being on the same spindle, one above another. A very little rise and fall is required; as the two valves need only to be opened to half the extent to which one would be required, comparatively slight action of the governor is necessary.

To obtain a knowledge of the condition of the vacuum in the condenser, a vacuum-gauge is used. This is a tube connected with the interior of the condenser, and passing through a cup containing mercury. The tube is continued upwards nearly to the end, and finished with a glass-tube closed at the end, the lower end of which dips into the mercury. The vacuum in the glass-tube is the same as that in the condenser. The atmospheric air pressing on the mercury, forces it up into the interior of the glass-tube, the rise being directly proportioned to the difference between the pressure of the *uncondensed vapour* in the condenser and the pressure of the atmosphere; a graduated scale, attached to the glass-tube, gives the degree of vacuum in the condenser.

For various details not here specified, as crank, connecting-rod, plummet-blocks, &c., we refer the reader to the number on MECHANICS, where he will find them fully illustrated. We now proceed to the description of the high-pressure engine. We have already adverted to the distinction between this class and that of condensing engines.

As the condenser, cold-water-pump, air-pump, cistern, &c., are dispensed with in the high-pressure engine, it is rendered more compact, and consequently less space is taken up by it. So early as 1720, Leupold produced a high-pressure engine; but the first invention which came into extensive use was the engine of Messrs Trevithick and Vivian, constructed by them in 1802. Since that period they have come into very general use, being much cheaper than condensing engines; and we may add, that the steam, after working the engine, instead of being projected into the atmosphere, may be used for warming premises, heating water for baths, and similar purposes.

The forms of high-pressure engines are various. The crank-overhead engine is the simplest form, and is very effective; engines with the crank under the cylinder are also much used; and a small size of this form, represented in fig. 23, is much used for driving small coffee-mills in grocers' shops. Their cost varies from £20 to £50, without the boiler. The most complex of all is the beam high-pressure engine. In general appearance it is much like the double-acting engine of Watt; but of course there is no condenser and its associated apparatus. High-pressure horizontal engines, the whole machinery of which lies horizontally, are coming much into use. Brunel's oblique-acting engine, we believe, is a very efficient form of high-pressure.

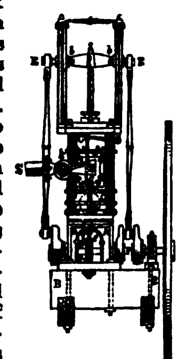

Fig. 23.

In fig. 24 we give a vertical section of a crank-overhead engine. The steam is admitted from the boiler to the steam or valve chest *bb*; in this chest the valve works, sliding steam-tight against the valve face of the cylinder *aa*. There are three steam-ports—one of these leading to the bottom, the other to the top of the cylinder; the third, marked *o* in the drawing, leads to the exhaust-pipe. The valve covers two of these ports at the same time, one of which is always the exhaust-port. When the valve covers the upper steam-port, and the exhaust-port, the steam rushes from the space of the cylinder above the piston, down the port, and through the exhaust-port to the atmosphere; at the same time the steam is rushing from the steam-chest down the lower port to the under side of the piston *vv*, which it presses upwards. On the piston *vv* reaching the top of the cylinder *aa*, the valve is changed to the position of the diagram to the right in fig. 26. The valve *a'* covers the exhaust-port *b'*, and the lower steam-port *d*; the steam is rushing from the space below the piston *vv*, through the port *d*, and to the atmosphere through the exhaust *b'*. The movement of the valve up and down is produced by the revolution of the eccentric and eccentric-rod *j, j* (fig. 24), the play of the valve being double the distance of the working-centre of the eccentric from its true centre. The revolution of the crank-shaft, *gq*, is effected by the crank *h*, and connecting-rod *g*; this latter being fastened

to the end of the piston-rod by what is called a *piston cross-head.* The parallelism of the piston is preserved

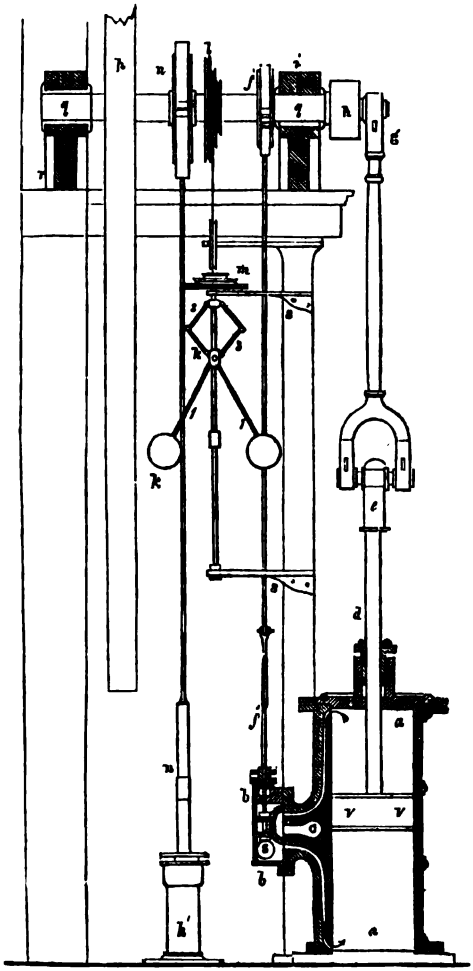

Fig. 24.

during its reciprocation by the cross-head sliding between two parallel guides, which are bolted to the upright framing that supports the crank and fly-wheel shaft. The crank-shaft is supported on bearings *q, q, r* (fig. 24).—The water is supplied to the boiler by the force-pump *h'*, which is worked by the rod and eccentric *m*.—The supply of steam is regulated by the governor *kk*. This is supported by two brackets 8, 8, bolted to the upright framing. A three-motion pulley, *l*, is fixed on the fly-wheel shaft, and a corresponding pulley on the upper termination of the governor-spindle. As the planes of motion of these pulleys are in opposite directions, a guide-pulley, *m*, is used to take the motion of the pulley on the shaft to that of the governor. As the governor is made to rotate rapidly, the balls *k*, by virtue of the centrifugal force, fly outwards, extending the arms or levers 1, 1, and depressing those marked 3, 3. Those are fixed by movable joints to a brass bush, which slides up and down on the spindle. The periphery of this bush—which is provided with projecting ruffs or collars—is embraced by the fork of a lever, which is connected with the throttle-valve fixed to the steam-pipe (fig. 15). The valve is thus closed—the admission of steam to the cylinder is lessened—the velocity of the engine is diminished—the governor rotates more slowly—the balls fall, lowering the arms 1, 1, and raising the arms 3, 3; and thus again opening the throttle-valve, allows the steam to enter the cylinder.

In fig. 25 we shew the method of attaching the eccentric pump-rod *mm* (fig. 24) to the pump-plunger; *aa* is the upper part of the pump-plunger; it is forked at its termination, the two forks *bb* being circular, as shewn at *ab'*. Holes are bored in these forks, through which the pin *e* passes, and which is secured by the cottar or key, *f*, being driven through the key-seat made at the end of *e*. Previous to inserting and securing the pin *e*, the end *cc'* of the eccentric-rod is inserted between the forks *bb*, so as to make the aperture made in it, as *d*, coincide with the apertures in *bb*; the pin, *e*, is then driven in, and secures them together.

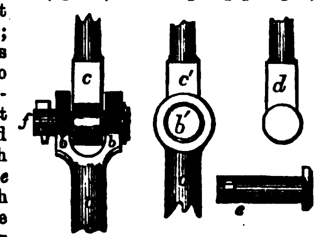

Fig. 25.

As there is greater danger to be apprehended from the use of high-pressure steam, the boilers of the engines are generally provided with two safety-valves—one locked up from the control of the engineer. The boilers are generally not so complex in their arrangements as those of low-pressure; indeed, in all their arrangements simplicity is the leading characteristic. They perform their work well, do not require such close attention, and with a reasonable degree of care, no danger of explosion need be apprehended. It may be mentioned here that locomotive engines for road and railway are all on the high-pressure system.

In high-pressure engines the steam is distributed to the cylinder by means of the three-ported valve. Fig. 26 shews the valve in the two positions, at the termination

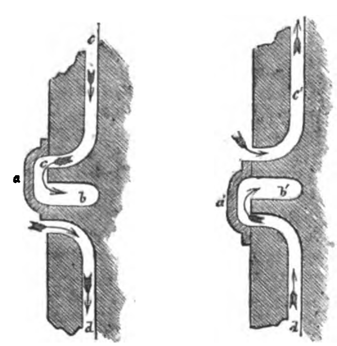

Fig. 26.

of the up-and-down stroke. The valve-face (see fig. 27), placed at the back of the cylinder, is planed perfectly true, and made very smooth. There are three ports in this: *c* leads to the upper part of the cylinder; *d* to the lower part; and *b*, the exhaust-port, leads to the external atmosphere. The form of valve is shewn at *a* and *a'* in fig. 26; the hollow part of which covers two of the ports, one of which is always the exhaust-port, the other the upper and lower ports alternately. The valve works within a casing, to which the steam is supplied; and is kept in close contact with the valve-face by means of a spring, or, instead of this, the pressure of the steam. In fig. 26, the sketch to the left hand illustrates the position of the valve when the piston is at the bottom of its stroke; the steam from the valve-casing, or steam-chest, as it is also called, is passing through the lower port and channel *d*, to the under side

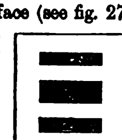

Fig. 27.

of the piston, while the steam from the cylinder space above the piston is passing out at the upper port *c*; but as this is covered by the valve, it is forced to pass out through the exhaust-port to the atmosphere. The sketch to the right shews the position of valve when the piston is at the upper part of the cylinder.

In high-pressure engines, the expansion principle is carried out by what is called expansion gear, which acts upon the steam-valve so as to cut off the steam at any desired part of its stroke. The forms of expansion gear are very numerous; we shall only describe a very simple arrangement. In fig. 28, let *a* be the steam-chest, *b* the exhaust-port, *c* the lower, and *d* the upper steam-port; a supplementary steam-chest *e*, with another valve called the 'cut-off,' is connected with the ordinary steam-chest *a*. The steam is supplied in the first instance to the supplementary steam-chest *e*; and any quantity can be admitted to the cylinder; that is, the supply cut off at any desired point of the stroke by merely adjusting the valve in the supplementary steam-chest, so that it will close the passage to the main steam-chest at any desired part of the stroke. This is effected by varying the throw of the eccentric which works the valve in the steam-chest *e*, this variation being adjusted by a simple mechanism which we have not space to illustrate here. Two eccentrics in this arrangement are thus required, the one which works the cylinder-valve in the steam-chest, *a*, being invariable in its throw.

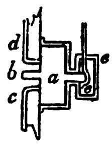

Fig. 28.

Steam is also used expansively in high-pressure engines by giving what is termed lap to the valve. This may be simply described as giving an extra length to that part of the valve which closes the ports—this lengthening being towards the steam-side; that is, the part towards the inside of steam-chest. Thus, in fig. 29, let *a* be the valve, *b* the port; if the valve is lengthened by a portion, as *c* (not shaded), it is evident that the port will be so much the sooner closed as the addition *c* is longer or shorter. To work effectually, the port should be fully closed when the piston has performed two-thirds of the stroke.

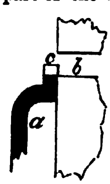

Fig. 29.

Another term which the reader may often meet with is the lead of the valve—what this is, we shall endeavour to explain. The action of the eccentric is such that its slowest speed is during the first portion of its throw; the consequence of this is, that the valve leaves a port very slowly at first, the progress of the steam to the exhaust-port being consequently retarded. As the steam, if allowed to remain long in the cylinder, would oppose the progress of the piston, and rob it of some portion of its power, it is necessary to arrange so that the steam will leave the cylinder as soon as possible after the completion of the stroke. The amount of valve-opening at this point is termed the lead of the valve, and is obtained by fixing the eccentric on the shaft more or less out of the ordinary line of centres.

A system of applying the expansive method of working to condensing-beam engines which may be deficient in power, now being extensively used, is that of having a supplementary steam-cylinder, connected with the beam in the opposite side of the beam-centre to that at which the usual cylinder is attached. The supplementary cylinder is supplied with steam at high-pressure, which, after working the piston, passes off to the usual or condensing cylinder, from which it passes to the condenser. This plan, introduced by Mr M'Naught of Glasgow, is found to be very efficient.

In order to convert the rectilineal motion of the piston into the circular one of the fly-wheel, with the intervention of as few movable parts as possible, a class of engines known as direct acting have been introduced. Nearly all high-pressure engines are on this principle, the object being to transmit the power of the piston immediately to the crank-shaft. A very common method of doing this is illustrated in fig. 30; a cross-head, *cc*, attached to the piston-rod, sliding between two parallel guides *a*, *a*, bolted to the framing. The lower end of the connecting-rod, *d*, is jointed to the cross-head, and the upper to the crank-pin (for method of making these attachments, see number on MECHANICS) of the crank *e*. There is much loss of power from friction by this method, which, however, can be reduced by careful workmanship. There is also a strain exerted on the piston-rod, in consequence of the thrust and pull of the crank—this is, however, in a measure obviated by lengthening the connecting-rod.

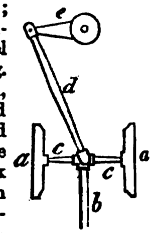

Fig. 30.

The best and simplest form of direct-acting engine is that known as the oscillating. As the end of the cylinder describes an arc of a circle—from the cylinder vibrating on centres in the direction of its length—the reciprocating motion of the piston-rod adapts itself to the position of the crank, and thus enables the piston-rod to be attached at once to the crank-pin without any connecting-rod being required. The centres on which the cylinder oscillates are termed trunnions, being hollow pipes, one of which is the supply, and the other the exhaust steam-pipe. The valve is worked by a curved link attached to the eccentric-rod, and so arranged as to be free from the effect of the cylinder oscillation. In some recently introduced oscillating engines of small power, the vibration of the cylinder is made to work the valve, thus further reducing the moving parts. In the section on marine engines, we give an illustration of an oscillating engine adapted to a steam-vessel.

To obviate certain supposed disadvantages of the oscillating engine, as the oval wearing of the cylinder from its constant movement, another form of direct-acting engine has been introduced, called the 'trunk-engine,' by which a fixed cylinder is obtained, and immediate connection of the piston-rod and crank. Fig. 31 illustrates this form: *aa* is the fixed cylinder; to the piston *b*, a hollow trunk, *cc*, is fixed, working through a stuffing-box. The diameter of this trunk is such that it admits of the vibration from side to side of the connecting-rod equal to the throw right and left of the crank *e*. The connecting-rod is attached to the piston at one end, and to the crank-pin at the other. The cylinder in this form requires to be of greater diameter than in ordinary engines, in order to get the amount of piston-surface; the steam acting only on what may be termed a ring of piston formed between the outside of the trunk and the interior of the cylinder.

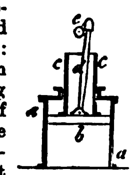

Fig. 31.

Before describing the locomotive and marine engines, we shall present a few remarks on another class not yet alluded to, vastly different in the principle of arrangement from those already described. The class referred to is the rotatory. In this form of engine, the cylinder, piston, crank, and fly-wheel are all dispensed with; and a series of chambers or cavities, supplied with valves and traps, revolving round or turning with a central shaft, constitute the engine. As its name imports, the motion derived from the steam traversing these chambers is at once circular or rotatory, no reciprocating motion being produced; and in this lies the chief merit of the invention. Engines of this kind admit of being made very simple, free from complex arrangements, and their power can at once be applied without the intervention of other machinery. The varieties of rotatory engines patented are very numerous; but, whether from any inherent error in their principle, amount of friction, or from some other cause, few of them have come into anything like extensive use. The simplest form of all

is that introduced by Mr Ruthven of Edinburgh. It is the same in principle as the æolipyle of Hero; and we believe the engines fitted up by this gentleman have given considerable satisfaction. Their use is not, however, extending.

Locomotive Engines.

The form of engine adapted to the railway differs from those already described, these being stationary or fixed in large vessels, while here the smallest bulk possible is essentially required, at the same time as little weight as convenient. Accordingly, we find that in the arrangement of these engines, all that apparatus is rejected which is intended for condensation, and therefore high-pressure steam is used.

In the arrangement or disposition of the parts of the boiler and engine, there are certain peculiarities which require to be described. It is necessary to premise, that the great object is to effect as speedily as possible the conversion of a large quantity of water into vapour; this is accomplished by arranging the boiler in a peculiar manner. It is not one large mass, as in the marine boiler, or land boiler, with a great quantity of water in the centre, but an oblong cylinder, through which are disposed a vast number of brass tubes of a cylindrical shape, amounting to about ninety in number, arranged horizontally. These tubes communicate with the furnace, and the heated air passes through them as it proceeds to the chimney, in which manner an immense quantity of the caloric is applied to assist in the evaporation of the water; so that the boiler might, nevertheless, be considered merely the same as the common one, but with the chimney subdivided into an immense number of small tubes passing through it to the large vent-hole or grand chimney. These tubes were suggested by Mr Booth, secretary of the Liverpool and Manchester Railway, and improved upon by Mr R. Stephenson, and constituted a great advance in the efficiency of the locomotive steam-engine.

In the sketch, fig. 33, is given a general exterior view of a locomotive, and in fig. 34 a longitudinal section of the apparatus. The boiler is seen forming the great bulk of the engine; its form is cylindrical, being about three feet in diameter, and eight in length. The numerous tubes, as they proceed through this part of the apparatus, are seen in transverse section in fig. 32, and longitudinal section, fig. 34. At the front of the engine is the smoke-box, terminating in the chimney above; and below, there is the steam-tube, and the cylinder and piston, which lie horizontally. At the back of the engine is the fire-box, almost completely surrounded by water, and immediately behind this is the railed space P on which the engineer stands. On the upper surface of the engine, proceeding from the hind part forwards, there is the steam-whistle X, by which notice is given of the approach of the engine. A little anterior to it is the man-hole, by which the boiler can be cleaned, and such repairs made as are requisite. Still further forwards, we arrive successively at the two valves V′, V, by which the safety of the boiler is secured. The first, V′, is always under the control of the engineer; but the second, nearer the chimney, V, is loaded higher, but completely shut up. A round spherical eminence, B, is then perceived immediately behind the chimney, called the *separator*, in which the steam gathers before it is conveyed by the tubes to the cylinder. The cylinders (two in number) are placed below the chimney, and lie immediately before the front wheels (A, fig. 34), and the steam passes to them by the steam-pipe S, whence, after moving the pistons, it escapes into the chimney. The reason why this tube rises so high in the large chamber is, that no water may descend to the cylinder, which might likely arise from the agitation the water suffers from the motion. At the point where the steam-tube in the hot-air chamber meets the connecting-pipe with the boiler, a regulator is placed, for increasing or diminishing the flow of steam.

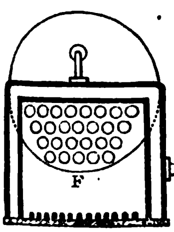

Fig. 32.

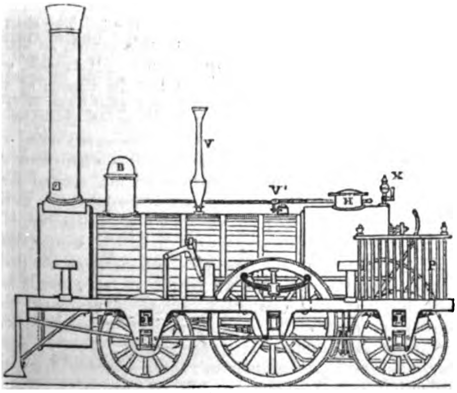

Fig. 33.

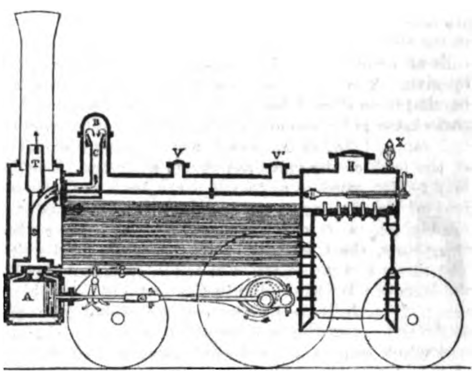

Fig. 34.

The steam, as it escapes from the cylinder by two pipes, meets in the common tube, and rushing upwards into the chimney, is in part condensed, and mainly contributes to the draught of the chimney, which otherwise would be totally inefficient to work the fire.

From the great number of the tubes which fill up the boiler, the locomotive engine is not attended with much danger in bursting; for these tubes being weak, compared with the external casing of the boiler, yield readily on any unusual increase of the elastic force of the vapour; the consequence is, that the fire is put out gradually. When one yields, a plug of wood is introduced, which is generally sufficient till the end of the *run*, or till arrival at the next station.

The size of the steam-cylinder is about twelve inches in diameter, and eighteen inches' stroke. The driving-wheels are usually six feet diameter; and some of ten feet diameter have been tried on the Great Western Railway. Three cylinder engines of great power have been introduced by Mr Stephenson, their speed being upwards of seventy miles an hour!

The engine is always attended by a tender, in which the coke and water are conveyed. The mode in which the different coaches are arranged may be seen in the number on INLAND CONVEYANCE, where a train is figured with the engine and tender.

The power of a locomotive is estimated by the quantity of water which the boiler can convert into steam within a given time. Between seventy and eighty cubic feet is

the average amount per hour; but in the Bristol railway, so much as 200 cubic feet are evaporated within the same time. The quantity of fuel consumed in Stephenson's engine is about ¼ lb. for every ton per mile.

The mechanism for effecting the backward as well as forward movement of the locomotive was formerly very complicated. The reversing gear is now, however, very much simplified by the introduction of the 'link-motion' of Mr Stephenson. Two eccentrics are fixed in the crank-shaft, one of which gives the forward, the other the backward motion of the locomotive. The ends of the eccentric rods *a*, *b* (C), fig. 35, are jointed to centres at the

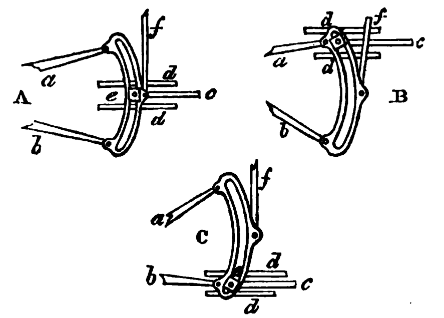

Fig. 35.

ends of a curved link, in the centre of which is a slot or opening. The valve-rod cross-head slides between two parallel faces *d*, and has a bush at its extremity, which slides between the slot of the link. By means of a lever, the link can be lifted or depressed, thus altering the position of the bush of the valve-rod in the slot: thus, the link may be depressed so as to make the bush at the lowest part of the slot, as at C; or raised so as to make it at the highest, as B; or when placed midway between these two points, the bush will be in the centre of the link. The throw of the eccentrics, *a* and *b*, being equal, when the bush of the valve-rod is in the centre of the link, the action is such that the two eccentrics neutralise each other, and no motion is imparted to the valve-rod; the only effect being to cause the link to vibrate on the bush as a centre. But when the link is raised by the lever, *f*, into the position B, the valve-rod is receiving the full power of the eccentric *a*, which may be called the forward eccentric, and the locomotive moves forward. When it is required to move backward, the link is depressed into the position C, when the valve-rod receives the full force of the backward eccentric *b*. It is evident that this apparatus is capable of being used for expansive working, the amount of throw of the valve being obviously capable of a large amount of variation between the position shewn in C and those in B and A. Expansive gear on this principle is much used.

A few historical notes on this department may not be deemed amiss in this place. The first practical locomotive for working on a line of rails (see INLAND CONVEYANCE) was that patented by Richard Trevithick in the year 1804. The railway on which it ran was at the colliery of Merthyr Tydvil, in Wales. Many of the arrangements and appliances of the modern locomotive are to be met with in this, its earliest form. One of the principal features of the locomotive of the present day—the blast-pipe by which the waste steam admitted to the chimney increased the draught—was used in Trevithick's engine.

It was, however, to the genius of the celebrated George Stephenson that the modern locomotive owed its existence. Others, doubtless, lent important aid in perfecting the mechanical details, but without the admirable inventions of Stephenson in connection with railways, the locomotive could never have arrived at its present efficiency. 'That the modern locomotive,' says Mr Scott Russell, 'could not subsist without the wrought-iron rail, and its multifarious appendages of chains, keys, locks, sleepers, switches, crossings, sidings, and turn-tables, is too evident to need proof. Without the smoothness of the rail, the engine would be jolted to pieces; and without the easy motion which it gives, the engine could not be made to draw a sufficiently profitable load to pay; and further, unless made of wrought iron, it would be impossible to attain the high speed of the locomotive without imminent danger. It therefore appears that the continuous wrought-iron railway and the locomotive engine were inventions intimately related to each other, and each a condition of each other's success. To Stephenson we are indebted for the chief features of both.'

In 1814, Stephenson, being pecuniarily assisted by Lord Ravensworth of Killingworth Colliery, constructed a locomotive which was tried on a tramway at the above colliery. This was subsequently improved, and tried at other places; but, in spite of the exertions of Stephenson to introduce them into use at various collieries, the mechanism was not sufficiently well arranged to render them economical and efficient.

The opening of the Manchester and Liverpool Railway, the engineer of which was Mr Stephenson, gave him another opportunity of bringing out an efficient locomotive, worthy of the new field of its operations. The result was the awarding of the prize of £500 for the best locomotive to the *Rocket*, the engine entered by Stephenson for the grand prize. This engine, which, with its own weight alone, traversed the railway at a speed of twenty-nine miles, created an interest in the new power which has never since then ceased to exist, and which, by directing the attention of such able mechanicians as Hackworth (to whom the locomotive owes so much), Hawthorn, and Fairbairn, resulted in establishing that wonder of modern times, railway-travelling.

Marine Engine.

In the steam-engines employed in the navigation of vessels, there are certain modifications which it is requisite here to notice.

The most striking peculiarity is the position of the beam in British steamers, which, instead of being placed above, is situated below, chiefly with the view of saving room, and is not single, but two, one at either side of the cylinder. To the upper portion of the piston-rod there is a cross-bar, which is placed transversely across the cylinder, at right angles to the long axis of the ship, or from starboard to larboard, in nautical language. From the extremities of this transverse bar, rods stretch down, connected interiorly to the termination of the beams, moving on pivots at both their connections with the cross-head and beams. The other extremities of the beams are attached to a cross-piece, on the centre of which the rod is fixed by which the crank is worked. The shaft of the paddles is firmly connected to this crank, so that it is worked along with the rod. In small vessels, only one engine is usually employed; but in vessels of considerable tonnage there are two, and their action is so

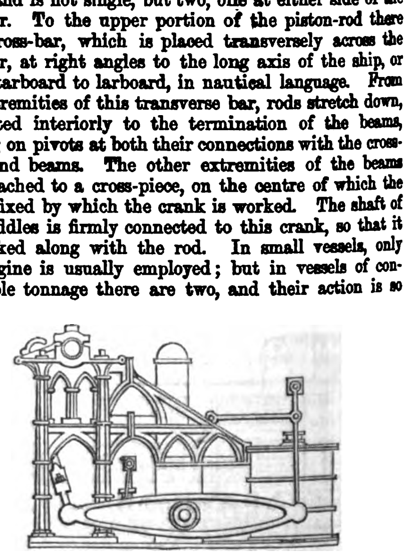

Fig. 36.

adjusted, that while the one is at its fullest strain, the other is in the reverse condition. In this manner the

motion of the wheels is preserved uniform and equal. These forms of engine are usually called condensing, the steam being worked at high-pressure, and then condensed, a result which is very readily accomplished, in consequence of the abundance of water.

Fig. 36 is a side elevation of a side-lever marine engine.

To avoid the great waste of room which the use of a side-lever engine involves, a great variety of direct-action engines have been introduced. By far the most efficient of these, according to good authority, is the oscillating engine; it takes up little space, and is economical in operation. Fig. 37 shews the application of this form to a marine engine. The trunk-engine has been also applied to marine-navigation.

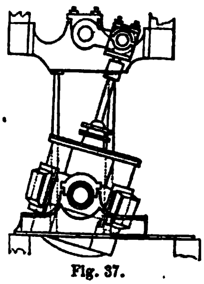

Fig. 37.

Boilers are differently arranged in steam-boats from those on land. In fig. 38 we give a diagram illustration of a form in common use. *a* is the fire-door, *b* the fire-bars, *c* the fire-bridge; the flame and smoke pass up by the space *d*, and return along the tubes *e*, *e*, to the chimney in the front of the boiler. Two of these boilers are placed back to back, by which arrangement a large amount of heating-surface is obtained in comparatively small space. It will be observed that the steam and water space is obtained rather by adding to the height than to the length, as in land boilers. A species of boiler, called the vertical, is being introduced into marine engines; in this, the boiler is of great height and small diameter; the furnace is situated at the lowest part, and the flame and smoke pass to the chimney flue through a series of vertical tubes surrounded with water.

There is a peculiarity in the arrangement of marine boilers, which it is necessary here to point out; this consists in the process of *blowing out*, as it is technically named. In sea-water there is a considerable quantity of saline matter, about 3 per cent., which, accumulating in the boiler, not only retards the process of boiling, but is apt to give rise to explosions. To obviate these imperfections, hot water is permitted to escape freely from the boiler at stated intervals, and as the discharge takes place from the interior surface, the greater portion of the saline matter is carried off. In this mode, a very serious obstacle was effectually removed. This was not done but at a considerable expense, the loss being estimated at nearly 1-54th part by Mr Tredgold; for it is apparent that an immense quantity of heat must have been lost in the warm water employed for this purpose, and not subsequently converted into steam. After all, the plan is only partially effective, as a solid incrustation remains on the bottom of the boiler so hard as frequently to break the shovels employed in its removal. This incrustation is the cause of much waste, for, from its bad conducting-power, the bottom of the boiler is often heated to redness before the required amount of steam is produced, thus causing not only loss of fuel, but rapid wearing of the boiler-plates.

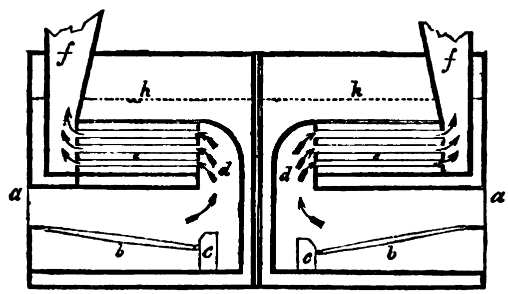

Fig. 38.

A very ingenious method has been invented by Messieurs Maudsley and Field, which preserves a uniform standard of the quantity of salt in the water of marine steam-boilers. This is effected by means of pumps, called *brine-pumps*, which are worked by the engine, and remove from the boiler the strong solution of salt and water. These pumps discharge as much salt, combined with the small quantity of water, as the feed-pumps supply to the boiler, so that the quantity of salt remains almost always the same. Further, before this hot brine is discharged into the sea, it passes through a tube included in another, which is the feed-pipe supplying the boiler from the sea, so that the greater amount of its caloric is imparted to the water, and it is reduced to nearly 100° before it is thrown out.

If the steam can be condensed merely by the application of cold water to the outside of the vessel containing it, it is evident that a boiler might be filled with pure fresh water on leaving port, and this water be converted into steam, back again into water, a second time into steam, and so on in succession, without ever coming in contact with salt. This has been effected by Mr Samuel Hall, who is the patentee of several improvements in connection with marine engines. His condenser consists of a flat vessel, in the bottom of which are a number of small apertures, and from these pipes in tubes are led to another similar flat vessel. Both vessels are air-tight. Into the top vessel the steam to be condensed is admitted, and passing through the tubes which are immersed in cold sea-water, it is perfectly condensed on reaching the under vessel, from which the newly formed water is drawn off by an air-pump. As the cold sea-water becomes heated, it is pumped off, and a fresh supply admitted. This invention, though severely tested, and found efficient, has not come into the extended use at one time anticipated for it. A condenser on the same principle has been introduced and economically worked on board of one of the Collins line of Atlantic steamers; it is known as Pirsson's.

The paddle-wheel by which the steam-vessel is propelled has undergone many modifications, for in the common mode in which the flat boards or float-boards are disposed, they both enter the water obliquely and leave it obliquely, occasioning a considerable loss of power; for it is apparent that their greatest effect must be when they are nearly in a vertical position. The complex nature of several of these wheels prevents their general employment.

The most important modification of the propelling apparatus is what is termed the *Archimedean Screw*, patented a few years ago by Mr F. P. Smith, and now very generally adopted. Vessels fitted up with screw-propellers present no unseemly paddle-boxes, are not

so liable to be damaged by collisions or by shot, and are as swift and easily managed as those propelled by the old paddles. The screw is formed by radial arms or blades, twisted, as it were, round a central iron axis. The screw thus formed is fixed parallel with the keel, at the stern of the vessel, below the water, and consequently out of sight. A variety of forms of the screw have been patented, chiefly differing as to the *pitch* or angle at which the blades are fixed on the axis. For sea-going vessels, the screw will soon, in all likelihood, be the only mode of propulsion adopted, as its advantages, either alone or as an adjunct to ordinary sailing, are numerous and decided.

In Great Britain, the engines adopted are those called *condensing*, and they usually work with a pressure of about 40 pounds on the square inch. In America, the high-pressure engine is generally used; and Stevenson states he was in a vessel on the Ohio where the common pressure used was 138 pounds on the square inch!

In estimating the work capable of being performed by a steam-engine, two methods are open for use—the nominal and the effective horse-power. The first is exceedingly unsatisfactory, and should be confined only to imply size. Mr Bourne's rule for finding the nominal power of an engine is as follows:—'Multiply the square of the diameter of the cylinder in inches by the cube root of the stroke in feet, and divide the product by 47; the quotient is the number of nominal horse-power of the engine.'

An important point necessary to be known in calculating the effective power of an engine, is the mean pressure in the cylinder during the stroke. This is obtained by the use of the instrument known as the indicator.

The *indicator* is a piece of mechanism devised by Watt, by means of which the force of the steam, and the state of exhaustion in the cylinder, are known at the different periods of the stroke of the piston. It is a small cylinder, 8 inches long and 1¾ inch in diameter, communicating directly with the cylinder, and supplied with a piston. If the force of the steam in the cylinder exceeds the pressure of the atmosphere, the piston of the indicator then rises, and if it be less, is depressed. A tracer is connected with the indicator, by which a curve is drawn on paper, indicating the variations occurring in the pressure of the steam, and from this the mean pressure is calculated. This instrument is now much used, as the only satisfactory method of knowing the working capabilities of a steam-engine. As the stethoscope to the medical man, so is the indicator to the engineer.

Different values have been given of the power of a horse;* but that generally adopted is, that it can raise a weight of 33,000 pounds one foot per minute, and therefore a steam-engine capable of executing that work is rated at 1 horse-power. On a railway, this power is considered equal to transport 400 tons one mile per day; or a horse draws 200 pounds at the rate of 2½ miles in an hour, continuously, over a pulley. The evaporation of a cubic inch of water, when converted into steam, affords a mechanical force capable of raising a ton one foot high. Fifteen cubic inches of water, therefore, when converted into steam, are equal to the power of one horse per minute, or 900 cubic inches per hour for each horse-power.

To evaporate this, from seven to twelve pounds of fuel are required in the same time (one hour); but in marine engines, the quantity consumed is about eight pounds, the proportion of fuel they consume being as two to three compared with other engines.

* The *medium* power of the horse is rated at 22,000 pounds raised one foot per minute; but 33,000 is the standard applied by engineers to the steam-engine.

Engineers possess rules for calculating the elastic force of steam and power of engines. The following may give an idea of the method of calculation:

To find the power of an engine, multiply double the length of the stroke by the number of strokes per minute, and we get the velocity of the piston per minute. If the engine works expansively, the mean effective pressure must be found. Multiply the square of the cylinder's diameter in inches by the mean effective pressure on the piston in pounds on the square inch, and by the velocity of the piston; point off three figures, and divide the product by 42, and the quotient will express the number of horse-power. Let the diameter of the cylinder be 36 inches, the length of stroke 4 feet, the number of strokes per minute 24, and the mean effective pressure on the piston 4 pounds per square inch, then

8 Feet × 24 = 192 per minute.

```

In connection with the working of engines, there is another term used, that of duty; it is frequently used as synonymous with the horse-power of an engine; the terms, however, are essentially distinct. By duty is meant the quantity of work done by the consumption of a certain quantity of fuel, time being left out of the calculation. In engines used for the purposes of manufactures, or for navigation, it is difficult to calculate exactly the amount of resistance which the machine encounters; but where employed for pumping water, their performance is more easily determined. The highest duty performed by an engine in Cornwall, at Wheal Hope Mine, was raising nearly 47,000,000 pounds one foot high by the combustion of one bushel of coal. Another engine at St Austell raised 95,000,000 pounds one foot high by one bushel of coal. This enormous mechanical effect was so unusual, that doubts arose as to the correctness of the report; and in the presence of a number of witnesses, the engine was again tried, when the result was, that it raised 125,500,000 pounds one foot high by the consumption of one bushel of coal.

Of the steam-power at present employed in Great Britain, it is almost impossible to form an accurate estimate; statisticians, however, reckon it as equal to about 2,000,000 horse-power—an amount of animal force which could never, in reality, be brought into full operation without extensive derangement of our whole economic system. It is difficult, indeed, to form an adequate conception of the advantages already resulting from the use of the steam-engine, still more to imagine those that are yet to result from its perfection and more extended employment. We have only to look around us to see its mighty influences visible on all hands. Navigation, travelling, automatic factory-labour, printing, mining, and a hundred other arts, have been brought to their present state only by means of this wonderful agent. In its adaptation to mills and factories, steam is doubtless more costly than water-power; but being independent of situation or seasons, it is in general circumstances preferable. Its placid steadiness, and the ease with which it may be managed, are also great recommendations in its favour. As a motive-power in the industrial arts, steam takes the precedence of all others; and, viewing it as an economiser of labour and time, it must be assuredly pronounced as the greatest of modern mechanical contributors to human progress and comfort.

CIVIL ENGINEERING.

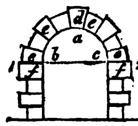
CIVIL ENGINEERING has been defined as the 'science of construction.' In this sense it deals with the designing and execution of all works, machines as well as structures; but its popular signification is much more limited. While the designing and execution of civil and domestic structures occupy the attention of the architect (see ARCHITECTURE); and machines that of the practical mechanic (see MECHANICS—PRACTICAL MACHINERY); the designing, and construction of roads, canals, railways, harbours, piers, docks, bridges, and the supply of water to, and the drainage of towns, are understood to be the special province of the civil engineer. It is to a notice of the principal features of those works which have so materially ministered to the social and political greatness of our country, that the present article is devoted. Of necessity, the limited space at our disposal will render our notices very brief; we can only point out the principal features of the various constructions, leaving altogether untouched the principles and theories on which they depend. The following general statement of the subjects with which the civil engineer should be conversant, will shew the reader that there are few professions which demand such a varied and extensive preliminary study, independent altogether of the time to be expended in acquiring a knowledge of actual practice.

Previous to entering the office of a civil engineer to acquire a knowledge of the practice of the art, the student should be thoroughly conversant with the following branches of science: Natural philosophy, including in this term the properties of matter, motion, and forces; mechanics, elements of mechanism; hydrostatics, hydraulics, pneumatics; practical mathematics, geometry; geology; mineralogy; mechanical drawing; and the various kinds of projection used in the preparation of working-drawings. To these may be added, as useful, a knowledge of meteorology, physical geography, architecture, and chemistry (see those subjects). On entering the office, and commencing the practice of his profession, the young student should avail himself of every opportunity of thoroughly investigating the application of those principles or theories to actual constructions, and to note carefully those modifications of practice induced by its various contingencies. In addition to those general sciences, he requires a particular knowledge of what may be called 'special studies'—as, surveying and levelling in all their branches; the construction of plans and working-drawings from data obtained by these surveys; and the drawing up of specifications and making out estimates of various works to be performed. The nature and properties of the various *building materials* should next occupy his attention; as stone, brick, wood, and the various metals, mortars, cements, paints. In regard to these, he will require to know the strains which they are capable of supporting; their durability, and the means of increasing it; and the most economical and quickest methods of making them available for the purposes to which they are to be applied. In connection with this department, the best modes of arranging the materials, and the calculations by which the sizes and forms of beams are ascertained, will also engage his attention. The theory and practice of masonry will next come under his notice, embracing the various methods adopted in raising safe and durable structures, and proportioning the forms and dimensions of their various components. In this department, the following are the principal points: Foundation—in ordinary soil, in wet or marshy soils, in water; enclosing-walls, retaining-walls, counter-forts, relieving-arches. Under the head of carpentry, the student will be called upon to investigate the general principles and theory of framing, and the methods adopted in practice in constructing the joints of framed work; and to calculate the direction and force of the strains to which certain beams will be subjected, and to proportion the sizes thereto. From this somewhat arbitrary arrangement of the branches of study to which the civil engineer is required to devote himself, will be gathered some notion of the labour involved in the actual practice of the art. We now proceed to notice the more prominent features of the several operations that the civil engineer has to direct, taking the subjects in the following order: Bridges—stone, iron, and suspension; Roads, Canals, Railways, Marine Engineering—comprising roadsteads, breakwaters, harbours, docks, the protection of sea-coasts, and river improvements; Sanitary Engineering, embracing supply of water to, and drainage of towns.

BRIDGES.

Before commencing the construction of a bridge, a variety of circumstances have to be considered by the engineer. As regards its position, in most cases very little latitude is allowed; where the choice is left to the engineer, he should be careful to select a site where easy approaches and good foundations for the structure can be obtained. The nature of the water-way will have to be carefully surveyed; soundings and borings being taken to ascertain the contour of the bed, and the nature of the strata underneath. In deciding upon the kind of bridge to be constructed, the engineer must be guided by two great considerations: 1. The keeping of the water-way clear for the passage of accumulated waters during floods, and, in the case of a navigable river, for the passage of vessels; 2. The avoiding of unnecessary contraction of the stream, so as to create currents which will exercise a prejudicial effect upon the banks of the river or the foundations of the piers. To aid him in his decision on the latter point, he must repeatedly test the velocity of the current at points, above and below the site of the bridge, in its various conditions, whether in times of floods or otherwise, deducing from his observations the velocity which the water will assume when passing between the piers of his intended structure. Having satisfied himself on all these points, the engineer proceeds to set out the line of bridge, and to apportion the number of *bays* or intervals into which the water-way is to be divided, and the form and dimensions of the arches. As regards the number of bays, the rule is, that their number should be odd, thereby causing less obstruction to the current by the absence of the central pier, which an even number of bays would render necessary. Gently flowing currents may have the bays narrower than those of quickly flowing ones. Arches are of different forms—the *semicircular*, *elliptical*, and *segmental*. An arch consists of the following parts (see fig. 1): The line 1, 2 is called the *springing-line; bc*, the *span;* the distance of *a* from the line *bc*, the *rise;* the inner curve, *bac*, the *intrados;* the outer curve is called the *extrados; d*, the *keystone; e, e*, the *voussoirs*, or ring-courses; *f, f*, the abutments, of which the upper stones are called the *impost* or *springing courses*. The *crown* of the arch is at *a*. A bridge is said to be on

the level when the arches are all equal in size and the springing-line horizontal.



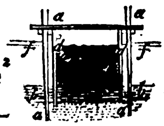


Fig. 1. Fig. 2. Fig. 3.

The construction of the piers and abutments from which the arches are to spring, next demands the attention of the engineer; and in connection with this, the most important point is to obtain a good and unyielding foundation. It is here that generally all his resources and skill are called into full play, as at this point the great difficulties of all large undertakings are met with. Where a rock or rocks can be made available, the matter is comparatively easy; but where the soil is soft and yielding, a variety of appliances are called into requisition. A very common method of constructing the foundations of piers, when these are under water, is by erecting what is called a *cofferdam*. Fig. 2 illustrates a section of this contrivance. A series of main piles, *a*, *a*, are driven into the soil, *bb*, enclosing the space on which the foundation is to be built; a row of inner piles, termed *sheeting-piles*, *d*, *d*, are driven into the interior of *a*, *a*, the space between the rows of piles being filled with clay puddling to make the cofferdam water-tight; the water is then pumped out, and the excavation for the foundation commences. The thickness of the piers is determined by the span of the arches, the height up to the springing-line, and the nature of the material of which these are to be constructed. They should be made as narrow as is consistent with the strength required to support the superstructure, so that the water-way may not be unduly contracted and currents formed, which would scour out the bed of the stream, and undermine the foundation of the piers. The thickness at the springing-line should not be less than twice the depth of the *voussoirs*, but if greater thickness is desired, the piers may be made hollow; this gives greater lightness, with strength sufficient to resist the vertical pressure of the arch. Any excess of load over this, only tends to exert a prejudicial pressure on the foundations of the pier. To preserve the bed of the stream around and between the piers, it is not an unusual practice to cover the surface with stones, thrown loosely in, of sufficient weight to resist the current. The *starlings* or *cut-waters* are the extremities of the piers just above the foundation, and the office of which is to divide the stream, without causing the formation of currents, and to guard the masonry of the foundation from the force of the water, floating bodies, &c. The best form is understood to be that of a semi-ellipse. Fig. 3 is a very usual shape. The arch-stones, or voussoirs, are supported till the keystone is put in, by a framing or *centre*. This consists of a number of vertical frames, called *trusses* or *ribs*, the outer surface of which is cut to the exact form of the intrados of the arch. The stones or voussoirs do not rest immediately upon this, but upon a series of timbers placed transversely, and called *bolsters*. In fig. 4, *a*, *a* are the back-pieces; *c*, *c*, the bolsters; *b*, *b*, the supports. When the keystone is put in, the centres are *struck*—that is, taken out. This is effected by striking out a series of wedges, on which they rest, so that the arch may be allowed gradually to settle; when this is done, the centres are quite removed, and the operation is complete. Into the architectural details—the cornice, &c.—we cannot here enter.

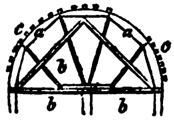

Fig. 4.

Iron Bridges.—In iron bridges the metal used is either *cast* or *malleable*, and in some cases a combination of both is adopted. The most celebrated example of a cast-iron bridge is that built over the Thames at Southwark. In this, 'each arch consists of eight ribs, and each rib is formed of fifteen pieces, which are of such depth that the rib is six feet deep at the crown, and eight feet deep at the springing. The metal is two and a half inches thick in the middle, and four and a quarter inches at the top and bottom of the ribs. The ribs are connected transversely by cast-iron tie-braces of the same depth as the ribs, but open in the centre of each; and in the diagonal direction, the ribs are connected by another series of ribs, so that each arch consists of a series of hollow masses or voussoirs, similar to those of stone-bridges. The whole of the segmental castings forming each arch, as well as the transverse and diagonal tie-braces, are kept in their places by dovetailed sockets, and long cast-iron wedges.' Bridges constructed in this way possess all the peculiarities of the stone-bridge. A materially different arrangement is that of the *girder-bridge*, on the same principle as a flooring-beam laid from wall to wall of a house. This form is much used for railways, the depth being so comparatively trifling as to make it peculiarly adapted for carrying the railway across roads or streams at a limited height above their surface. The full extent of bearing to which cast-iron girders are considered safe is forty feet; but by having a combination of wrought-iron tie-bars with the girders, a span of seventy feet has been crossed. This combination is not considered safe, and is not much used. The most generally adopted method in *wrought iron* is the *tubular girder*, invented by Mr William Fairbairn of Manchester. In this structure, the plates of metal are riveted together by means of what the inventor calls *chain-riveting*. Wrought iron being less able to bear compression than extension, the upper part of the tubular girder, when wide spans have to be crossed, is formed with rectangular cells, two or more in number. The forms in which malleable iron is applied to bridge-construction are various, and have formed the subject of numerous patents. In the wrought-iron tubular bow-bridge of Mr Harrison, the roadway is supported by an arched tube of iron, which rises above it, the *chord* of this arch being also formed of a tube, and the two being connected by a series of iron bars and braces. When used for railway purposes, there are three of those arched tubes placed parallel to one another, one dividing the *up*-and-*down* lines. The most celebrated instance in which wrought iron has been used, is that of the Britannia tubular bridge on the Chester and Holyhead Railway.

Suspension-Bridges.—In those, the roadway is suspended by vertical chains, connected with other chains stretched across the river or opening. From the principle on which the structure depends, all vertical strains are resolved into tensions in the direction of the curve; the adaptation of the materials, therefore, to the strains to which they are subjected can be more accurately determined, and much of the dead or unproductive weight, unavoidable in bridges on the arch principle, dispensed with. From the manner of construction, repairs are also easily carried out. The permanency of suspension-bridges is, however, liable to be endangered from the variations of form induced by changes of temperature, and from undulations caused by the traffic and the action of gales of wind. In fig. 5 we give the usual arrangement of a suspension-bridge: *b*, the roadway, suspended by vertical chains from the curved chains, *c*, *c*; these are made to rest upon *iron saddles* supported in the towers, *a*, *a*, and

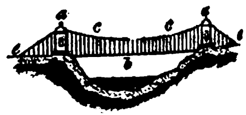

Fig. 5.

led down in the direction of *ee*, and firmly fixed into anchoring masses in the ground. The curves, *c*, *c*, may be formed of one chain or of several, and these may be either round or flat; flat bars are the most generally used. They are put together in the form of long links, connected together by bolts and plates; the bars forming each link being placed side by side, the suspension-bars for supporting the roadway may be either round or flat, and jointed in two or more lengths, to allow of their accommodating themselves to the motion of the bridge. Instead of iron-bars, wire-cables are much advocated by some engineers—a number of wires being placed side by side, so as to assume a cylindrical form, and kept together by an exterior wire. To the foot of the suspending-chains, cross-bearers are connected by stirrup-pieces; on these, planks are laid to form the roadway. Diagonal ties are generally placed between the cross-bearers. These, with trussed parapets above the roadway, and in some cases below it, prevent, to a considerable degree, the undulations caused by winds, &c. In connection with the erection of the Hungerford Suspension Bridge, many improvements were introduced; for a full account of these, see Mr Law's *Civil Engineering* (Weale).

ROADS.

When the construction of a road has been decided upon, the first duty of the engineer is to collect information to guide him in determining the best route it should take; in order not only that it may be constructed as level as practicable, and as economically, but also that it may afford facilities of communication in its route to as many towns and villages as possible, without interfering materially with the main object, which is the connection of the two extremities by as straight a line as can be obtained. This information is generally got by going over the district, and, with the aid of a good map, noting the number and situation of rivers, other roads, &c., the direction of the valleys and rising ground, and the general geological features. This general survey enables him to decide upon two or more routes which appear to him likely to be beneficial. These he surveys, and levels carefully, taking, wherever necessary, what are termed *cross-sections*, so that he can ascertain from the sections thus obtained whether any deviation from the proposed line would be advantageous. Noticing carefully the peculiarities of the *trial-lines*, he decides upon the line to be followed, which is then staked out on the ground by driving wood stakes, which mark the *centre line* of the intended road. The line thus marked out, is again carefully levelled; and from the data obtained, a section is constructed which shews the exact contour or outline of the undulating surface. From this the engineer is able to decide as to the exact line of surface the road is to have when constructed; which he endeavours so to arrange, that it may be as level throughout as possible, and the adjoining cuttings and embankments balance each other; so that the earth obtained from the former may serve to construct the latter. In the chapter on the plans and sections of railways, in the present number, the reader will find much that is applicable to the present subject.

As to the amount of ascent or descent admissible, it is generally restricted to from one inch in a yard to, at most, one inch in a foot. In order to obtain ascents not exceeding these, it is necessary, in our uneven country, to wind up a hill, instead of going directly over it. Along the side of a hill, is considered the most advantageous ground upon which a road can be constructed, provided the hill is not too steep; because what is taken from the upper side, serves to form the embankment on the lower side.

The junction of one road with another requires a little attention: it should always be made at right angles, if possible. All engineers agree that plantations of trees should not be made close to roads, as they prevent the exposure to sun and wind, which is necessary to keep the roads in a dry state; but the distance from the sides where trees cease to have a prejudicial effect, depends on the elevation of the country, the soil, the breadth and inclination of the road, as well as its direction. An elevated situation is always more exposed to winds than a level or hollow. A broad winding road has chances of the direct influence of the sun and wind, according to the obliquity of its angles; a road running north and south, though planted closely on both sides, will enjoy the sun during a part of every day in the year; one running east and west, planted on the south side with trees forty feet high or more, will enjoy no sun during the winter months.

In addition to levels, the points to be considered in laying out a road are—1. The breadth; 2. The form or *section*; and 3. The construction and material of the road.

1. The width of the road is regulated partly by the requirements of the traffic, and is partly a matter of taste and convenience, but it should not be less than thirty-three feet, to allow a free passage of vehicles in different directions. On all the good roads in Britain near towns, a side foot-path, protected by a curb-stone, is added to the ordinary breadth.

2. The section or form of the road is a disputed point among engineers: generally it is convex—the convexity, however, being comparatively slight. Mr Walker recommends it to be as flat as is consistent with good drainage. In most localities, the convexity will rarely exceed four inches—that is, the middle should be four inches higher than the sides. An idea of a perfect road may be formed from a frozen canal, where flatness, smoothness, and hardness are combined. Roads cannot be made with all of these perfections, but they should always be kept in view; for the nearer we approach to this standard, the less will be the draught. Macadam says, roads should be made as flat as possible. 'Where a road is made flat,' he says, 'people will not follow the middle of it, as they do when it is made quite convex, which is the only place where carriages can run upright, by which means three furrows are made by the horses and the wheels, and the water continually stands there; and I think that more water actually stands upon a very convex road, than on one which is reasonably flat.'

As the best form, Mr Law recommends the section to be constructed by two lines inclined from the side to the centre, at the rate of 1 in 30, these being united at the crown of the road by a segment of a circle described by a radius of ninety feet.

3. *Construction.*—There are two methods in use, very diverse in character, the one introduced by Telford, the other by Macadam. In that of the former, it is considered essential to have a firm, hard, and dry foundation, on which to place the road-materials; in that of the latter, it is immaterial whether the substratum is hard or soft—indeed, Macadam stated that he rather preferred a 'soft one to a hard one.' The point is a disputed one among engineers, each plan having its strenuous advocates; it is right, however, to state, that in this country the opinion is most favourable to Telford's plan, while that of French engineers is in favour of Macadam's.

Previous to laying down the upper material of the road, it is necessary to carry out plans for draining—a matter of the greatest importance. To insure this being effectually done, a series of trenches should be cut across the line of road, the sides of which should slope outwards, as in fig. 6, at *aa*; the trenches should have an

Fig. 6.

Fig. 7.

inclination from the centre to the sides of the road,

and a communication with the side-ditches. A tubular drain, *b*, or drain formed of tiles or stones, is placed in the bottom of the trench. Where roads are drained in this manner, the side-paths may be drained by having a slope towards the road, at the side of which an open channel is made, into which the surface-water runs; from this channel it is led by a small vertical drain, covered with a grating, and which communicates with the cross-drain. In fig. 7 we give a section of a road: *b*, the road; *a*, *a*, the fences at the side; *d*, *e*, the ditches into which the drain, *f*, discharges; *h*, the drain of the path. When the ground is of a very soft, wet, or clayey nature, this plan of drainage is the most effectual. A simpler plan is shewn in fig. 8: *a*, the road; *b*, open

Fig. 8. Fig. 9. Fig. 10.

channels made at each side, into which the surface-water drains; from which it escapes, by *gully-shoots* placed at intervals, into drains or open water-courses. In improved constructions, a *trap* is placed at these gulley-shoots, as at *c*, the water being led by a small tubular drain to a drain *d*, which conveys it where required.

The road being brought to its proper level, and the *formation surface* well drained, the upper surface is next to be put down—a firm, hard foundation being, by the majority of engineers, considered as essential. This may be obtained by using stones in the way adopted by Telford; or concrete, as used by some engineers, where stone is not so plentiful. The following extract from one of Mr Telford's specifications will shew his method of securing this firm foundation: 'Upon the level bed prepared for the road-materials, a bottom course, or layer of stones, is to be set by hand in form of a close, firm pavement; the stones set in the middle of the road are to be seven inches in depth; at nine feet from the centre, five inches; at twelve from the centre, four inches; and at fifteen feet, three inches. They are to be set on their broadest edges lengthwise across the road, and the breadth of the upper edge is not to exceed four inches in any case. All the irregularities of the upper part of the said pavement are to be broken off by the hammer, and all the interstices to be filled with stone chips, firmly wedged or packed by hand with a light hammer; so that when the whole pavement is finished, there shall be a convexity of four inches in the breadth of fifteen feet from the centre.' Where stone is scarce, a concrete composed of gravel and lime, in the proportion of four parts of the former to one of the latter, and carefully laid down to a depth of six inches, will form a firm foundation. Half of the breadth of the road should only be done at a time; and before the concrete is thoroughly dry, a three-inch layer of hard gravel or broken stone should be placed upon it, so as to incorporate and bind with it; a second three-inch layer is then added. The next point to be attended to is the covering or outer crust which protects this sub-road, and which forms the part on which the traffic is carried on. It is admitted on all hands that the best material for this purpose are angular stones, as introduced by Macadam. These stones should be of such a size as to pass freely through a ring two and a half inches diameter, and are best when made out of granite, whinstone, or basalt, which possess the quality of toughness as well as that of hardness.

In some districts, gravel only is available as an outer covering. In this case, it is necessary to bind it together; which is effected by using loam or sand to fill up the interstices. As before mentioned, in Macadam's plan, no foundation is prepared, but the broken stones are at once laid upon the road; the bottom coating being generally of larger sized, and also of softer stones, where the difference of expense of procuring harder materials is of importance. The covering of this kind of material, technically called *road-metal*, should be spread to a depth of from six to ten inches, as may be found necessary, and raked smooth on the surface.

For some time after a road has been laid with fresh materials, it presents a rough surface, unpleasant enough to travel on; but this roughness is gradually abated; the small stones are crushed into a compact mass; and, finally, the road is smooth, hard, and level. A point of some importance for the early attainment of this result, is to cause the traffic to be spread over the whole surface of the road, and not allowed to run in one or two lines of tracks; while the ruts that are formed in the loose materials are filled in as frequently as possible, until the whole breadth of metalling is brought to one uniform surface. Rain is a great enemy to macadamised roads, and particularly so when accompanied with much traffic. The water softening the material, it is thus more easily abraded by the action of the horses' feet and of the wheels, which soon creates a layer of liquid-mud. If this mud is allowed to lie, it continues to keep the metal below in a soft state, and makes it more easily cut up and damaged. With regard to *fences*, the following is the deliverance of a good authority: 'Fences are necessary along the sides of a road in all enclosed countries; but they should never be allowed to rise higher than four feet on common roads. It is absolutely necessary that the air and sun have free admission to a road; besides, where the fences are high, it gives a sweeping power to the wind, which is not beneficial.'

Paved Roads in Cities.—Where the traffic is heavy, as in the majority of our manufacturing and seaport towns, macadamised roads are soon put out of repair, and are, moreover, dusty in summer and muddy in winter. Paved roads are therefore used, in which the upper covering, as *cc*, fig. 9, consists of oblong blocks of stone resting on a well-prepared firm foundation—a point still more essential in a street than in a country road. A curb-stone, *b*, divides the road from the side-walk or pavement, *aa*, which should slope from the houses to the road, in order that the water may be quickly carried off. In making a paved road, the first step is to remove the soil to a depth of at least a foot, leaving the surface with a slight convexity. Where the soil is soft and clayey, the depth should be greater, in order to receive a layer of fine gravel or sand. On the bed thus prepared, a layer of broken stones should be laid, four inches thick, and consolidated by the passage of vehicles over it before the second and third layers are put on. When the third layer is well consolidated, a layer of gravel is placed to receive the paving-stones, which should be of as uniform dimensions as possible, and the size of which varies according to the traffic. Narrow stones make a better and more durable road than wide ones. The stones are laid in courses from the sides to the centre, and well rammed by a heavy rammer. For first-class work, after each stone is thus rammed down, and a *form* made for it, it is removed, and the side of the stone against which it is to rest covered with good hydraulic mortar; or the stones may be bedded in mortar. In ordinary work, the stones are merely rammed down, and a thin grouting of sand and lime, or melted asphalt, poured over the surface. Where the street is much inclined, the traffic is facilitated by putting down tram-ways of flagstone; and by placing the paving-stones with wide joints, so that a series of grooves are formed, giving a good hold for the horses' feet.

Of late years, a variety of patents have been taken out for forming the outer surfaces of roads of wood-blocks. This kind of pavement was too zealously introduced at first, without mature consideration of the means by which it could be made lasting; and from the failure consequent upon a too hastily adopted practice, the system was as quickly condemned. With a proper foundation, there is no reason to doubt of the success of

wood-pavement in districts where the traffic is not of a peculiarly heavy description. Asphalt pavements have also been tried, but not with much success: they are found to give way rapidly under heavy traffic; and they labour under another disadvantage, in not being easily broken up and replaced when the repair of pipes, &c., is necessary. Recently, cast-iron blocks have been introduced as substitutes for stone, and, according to trustworthy reports, are likely to be useful in many situations.

CANALS.

Many of the preliminary operations of the engineer in carrying out the construction of a canal, are similar in their nature to those required for roads and railways—as the survey of the ground, and the preparation of the working plans and sections. There are, however, certain special features connected with canals which require to be carefully attended to. The most important of these are: First, The nature of the soil through which the canal passes; some soils being so porous as to necessitate considerable outlay to prevent leakage. Secondly, Water can be retained only in a perfectly level channel; and as few districts will admit of this for any great distance, where a break occurs, it is necessary to meet the difference of level by a perpendicular lift, through the medium of a contrivance known as a *lock*. This, as will be explained hereafter, involves the loss of a large amount of water, to meet which, and to provide for waste by evaporation and percolation, the canal requires a *feeder*, a species of auxiliary canal, which conducts supplies of water to the *summit level*, or highest point in the route. The water is there admitted into the canal as required, or is stored up in a reservoir to serve as a reserve supply in time of drought.

The section or form of the canal varies according to circumstances—usually it is in the form shewn in fig. 10: *abcd*, the water-way; the towing-path is shewn at *e*; the side-drain at *f*; and *g* represents the face of cutting through which it is supposed to pass. The width of the water-way at bottom should be equal to twice the width of the boats; the width at top, such as to allow of two boats passing with ease. The slope in some works is not carried up to the level of the towing-path, but a horizontal bench is left about a foot above the water level; this is sometimes planted with aquatic plants, or paved with stones, to protect and strengthen the sides. In certain soils, to prevent filtration the bottom and sides are lined with a puddling of clay. This prevention of filtration, in cases where the canal is carried along an embankment, is of the utmost importance, as, if allowed to go on, it may speedily destroy the whole embankment. Fine sand sprinkled on the water is found to sink and stop up crevices pretty effectually. In some strata it is, however, necessary to line the canal with masonry.

Locks are rectangular chambers, of width and length sufficient to admit a boat easily; the depth of a lock is regulated by the amount of fall, or difference between the level of the upper canal, *aa*, and lower, *bb*, fig. 11.

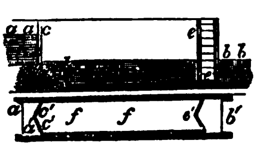

Fig. 11.

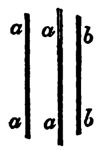

Fig. 12.

The walls of the lock are usually made with a slight batter or slope, and terminated near the upper gate, *cc*, by a vertical wall, *d*; this projects above the level of the bottom of the upper canal a few inches, and presents an angular surface, termed the *mitre sill*, against which the gates close. The gates, when closed, form an angle, as *c'c'* in the plan; in this way they mutually support each other, and the pressure of the water tends to keep them all the more firmly closed. In constructing the retaining-walls of locks, two things have to be guarded against—the pressure of the earth outside tending to force them in, and that of the water inside, acting in the opposite direction. The floor is usually concave. The recess made in the *head-bay*—as the upper part of the lock is termed—is called the *gate-chamber*, as *c'c'*, to admit of the gate falling in it, so as to keep the water-way quite clear when the gates are open. The gate turns on centres or pivots in the corner of the recess, which is termed the *hollow quoin;* and is curved, to admit the heel or quoin post of the gate to move freely, and at the same time allow no leakage. Two methods are in use for emptying and filling the lock-chamber: (1) by means of sluices in the gates themselves; (2) by drains or culverts leading from the upper canal to the lock-chamber, and from this to the lower canal—the flow of water through the culverts being regulated by valves. Each plan has its advocates; the first is more easily repaired. The lock-gates are closed either by windlasses, or, as is more usually the case, by balance-beams, which are connected with the mitre and quoin posts, and project considerably over the side of the chamber; these projecting beams are used as levers by men who press against them, and thus open the gates. Where a canal enters a river, great attention must be paid to the construction of the lock, which is here termed a *tide* or *guard lock*, and is provided with double gates, so that boats can pass either way according to the level of the river, whether it be above or below that of the canal. The following is the mode of operation of the ordinary lock we have above described, and illustrated in fig. 11. Suppose a boat is to pass from the lower to the upper level, the gates, *e*, *e*, are opened, and the boat is passed into the chamber *ff*; the gates, *e*, *e*, are then closed, as at *e'* in the plan. The sluices in the upper gates, or the valves in the upper culverts, are then opened; and the water rushing into the chamber *ff*, gradually fills it, till the level is equal to that of the upper canal, *aa*; the upper gate, *cc*, is then opened, and the boat is floated into the upper canal. If another boat is now to be passed from the higher to the lower level, it is at once floated into the chamber *ff*. The upper gates, and the sluices, or culverts, are then closed, while the sluices of the lower gate, or the lower culverts, are opened, and the water flows into the lower canal, till the lock-chamber is emptied, down to the level of the lower canal. The lower gates, *e*, *e*, are then opened, and the boat is floated to the lower canal. Here it is evident that a quantity of water is passed from the higher to the lower level, and a certain waste involved. To prevent this, a variety of means have been proposed and adopted; some of them to economise the loss, others to supersede the use of locks entirely, by certain arrangements of mechanism. In America, inclined planes are used, in which rails are laid down, and the boat, placed in a *cradle*, is pulled up, and delivered to the higher level. A somewhat similar plan has been adopted on the Monkland Canal in Scotland—not with a view, however, altogether to supersede the locks, but to save time and water by passing the empty boats from a low to a high level, the traffic in this canal being all downwards. The *caisson* containing the boat is hauled up by the power of two high-pressure engines at the top of the incline. Another plan, in use at the Grand Western Canal, may be noticed here. The principal feature is the employment of two tanks or caissons capable of receiving a boat, and suspended in such a way by chains passing over pulleys as to balance each other when both are full of water. When a boat is required to pass—say from the high to the low level—one of the tanks is brought up to the level of the upper canal; and by peculiarly ingenious mechanism the boat is passed into

it, *a portion of water equal to the weight of the boat* (see HYDROSTATICS) at the same time passing out of it. The two tanks—one containing water only, the other a boat with a portion of water—still, therefore, balance each other. To make an excess in the weight of the upper, a portion of water is allowed to pass out of the lower tank: the machinery being released, the upper tank with the boat descends, and the lower one ascends. The tank is, by the same means as above alluded to, connected with the lower canal, into which the boat then floats. This plan, the invention of Mr James Green, effects a large saving of water and time, a boat being lowered in three minutes a fall of 46 feet, which would take six locks and half an hour of time. For full working details, see Mr Law's work on *Civil Engineering*. In some cases, the method adopted for saving water during lockage is a pond placed alongside the lock, communicating with it by a culvert provided with a sluice. When the lock is full, and the boat to be lowered to the low level, instead of opening the sluice in the low gates, allowing the water to run into the lower canal, the sluice connecting the lock with the pond is opened, and the water runs into the latter until the level in the lock and pond is equal. This sluice is then closed, and the remainder is allowed to run into the lower canal in the usual way. On a boat being lifted from the low to the high level, the low gates are closed, and the pond-sluice opened, when the water rushes into the lock-chamber till the level in both is equal; the remainder of the water is supplied, as usual, from the upper canal, the pond-sluice being closed, and the high-gate sluices being opened. By this arrangement, about one-third of the water is saved. By having two ponds, one on each side of the lock-chamber, and of unequal depths, into which the water is admitted alternately, one-half may be saved.

Where the fall is great, a chain of locks is used, forming a kind of water-stair; the upper gates of the lowest forming the lower gates of the next highest lock, and so on. Where a valley is to be crossed, instead of using a series of locks to descend, and another series to ascend, the canal is formed on a series of arches, which is termed an aqueduct. The most celebrated structure of this kind is that designed by Mr Telford, for carrying the Ellesmere and Chester Canal across the valley of the Dee. It is upwards of 1000 feet long—the highest portion being 127 feet above the level of the river. The principles upon which aqueducts are constructed, are similar to those already described under the head of Bridges in the present article.

RAILWAYS.

In the number on INLAND CONVEYANCE, will be found notes on the historical, commercial, and social considerations connected with railways; it is our duty here to enter briefly into the subject of their construction, a matter which belongs exclusively to the profession of the civil engineer. This we propose to notice under the following heads: 1*st*, The laying out of the line, with the methods adopted to save material and to secure its economical working. 2*d*, Cuttings and Embankments. 3*d*, The boring of tunnels. 4*th*, The raising of bridges and viaducts. 5*th*, The permanent way.

1. *The Laying out of the Line.*—The correct theory of a railway is, that it shall be level from end to end, and that it shall be in a direct line. Accordingly, in the earlier constructions, vast sums were expended to have level lines, avoiding as much as possible all inclines or *gradients*, as they are technically termed. Such, however, have been the vast improvements effected, of late years, in locomotive mechanism, that considerable modifications in this department of railway construction have been introduced; so that gradients of a class which formerly would have been set down as impracticable, are now in almost general use. Indeed, in opposition to those engineers who hold that lines should be as level as possible, on the ground that they will be most economically worked, many now contend that the system of making lines with alternating steep and easy gradients, within certain limits, is more economical in working, inasmuch as the vast outlay in making cuttings and embankments is in a great measure avoided, and the capital thus saved more than compensates for the extra cost of locomotive power, while the speed lost in ascending may be gained in descending. The lines constructed on this principle are favourable in their results to its general adoption. In cases where the situation of one terminus is at a considerable elevation above that of the other, it is a matter of dispute whether the best plan, where the nature of the country admits of both, is to spread the inclination over a great distance, or to concentrate it in a few steep gradients, which may be overcome either by stationary engines or additional locomotives. In view of the fact that, in general cases, the load drawn by locomotives must be regulated by the steepest gradient they have to overcome, eminent engineers are now beginning to advocate the latter plan of having a few steep gradients with extra assistance at these points, the remainder and easier part of the line being traversed by the locomotive unaided.

As gradients are deviations from the theoretical level of a railway, necessitated by the exigencies of the country through which it passes, so curves are deviations from the straight line, which forms the other theoretical requirement. All deviations from the direct line must be in easy curves, abrupt bendings not being admissible, from the circumstance that the axles of the carriages are always parallel. This necessarily limits the curve which may be necessary to change the direction, as every bend of the tracks must evidently cause some lateral rubbing or pressure of the wheels upon the rails, which will occasion an increased friction. As the wheels are fixed to the axles, so that both must revolve together, the wheel that moves on the outside of the curve or longest rail would slide over whatever distance it exceeds the length of the other rail, but for a peculiarity in the formation of the wheels, which are keyed upon the axle, so as to have a slight play between the rails, and are formed of a conical shape, the larger diameter being close to the flanges, so that when the flange of one wheel is pressing against the outer rail, the other wheel on the same axle is running on that portion of it where the diameter is smaller, and thus a greater space is traversed by the wheel on the longest rail, and the pressure against it diminished. Still further to counteract the tendency of the carriages to press against the outer rail of a curve, or even to fly at a tangent off the rails altogether, the outer rail is elevated in proportion to the rapidity of the bend.

Formerly, curves of less than a mile in radius were considered dangerous; experience, however, has shewn that they may be made much less. Dr Lardner found that even with a radius of half a mile, there was no appreciable augmentation of the resistance at any speed attained. Curves of 220 yards radius have been traversed for years with safety, at the usual speed.

In laying out a railway, another point attended to is the economisation of the material; to effect this, the amount of cutting and embankment should be as equal as possible, and each cutting have a corresponding embankment near it, to which the removed earth may be taken at as little cost as possible; thus avoiding the necessity for raising banks of waste earth from the cuttings on the one hand, or for buying land to excavate for raising embankments on the other. The width to be given to the surface of the road depends, to some extent, on the width of gauge adopted. The principal gauges used in Britain are what are known as the 'broad' and the 'narrow.' The broad gauge is that adopted on the Great Western, having the distance between the rails 7 feet; the narrow gauge is 4 feet 8½ inches, and is that which is followed by the generality of

railways in the island. Throughout Ireland there is a uniform gauge of 6 feet 2 inches. It is an unfortunate circumstance that uniformity of gauge was not established in Britain; the want of it gives rise to great inconvenience in carrying on the 'through' traffic. In fig. 12, which shews at the same time the relative proportions between the broad and narrow gauge, we give an illustration of one of those expedients by which the carriages of the narrow-gauge line can be made available on the broad, and *vice versâ*: *aa* shews the narrow-gauge line, *bb* the extra line of rails. This is the plan adopted to join the Great Western line with the previously laid narrow-gauge line from Gloucester to Cheltenham. A very ingenious arrangement is made at the point of junction, by which the broad and narrow gauge carriages take their respective rails without requiring any attendance. It is difficult to state which of the two gauges is the best; each has its strenuous advocates; and the question has been discussed, both in parliament and at scientific meetings, with more warmth than the dignity of the eminent men engaged in the dispute seemed to warrant. Although in point of steadiness of motion and of safety at high speed, the broad gauge has advantages over the narrow, it would seem that the latter is, on the whole, best calculated for the business of the country, and the extension of the benefits of railway communication to agricultural districts. In point of cheap construction, the advantages are all on the side of the narrow gauge; the extra cost involved by the broad may be set down at from a fifth to a seventh of the cost of the narrow.

An important duty of the civil engineer is the preparation of the plans and sections, which require to be laid before parliament when application is made for authority to construct the railway. To aid him in this, the engineer procures an Ordnance or other map of the district through which the railway is to run, on which he marks the direction of the line, and ascertains the best method of laying down the base-lines for the survey from which the plan is made. The operation of taking the levels is then gone through, and the section prepared from the observations. In the parliamentary plans, the direction the line takes is accurately laid down, but a limit of deviation equal to 100 yards on each side of the line is allowed, and five feet in the section; in town districts, however, the limits of deviation are less—thirty feet, and two feet section. In fig. 13, we give a sketch of a plan of a line, in which *ab* is

Fig. 13.

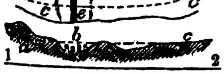

Fig. 14.

Fig. 15.

the line of railway passing through a country district; *cc*, *dd*, limits of deviation; *ee* shews it crossing a river. In fig. 14, we give the section, 1, 2, being what is called the *datum line*, from which the heights to the surface are measured. At *a*, the line is shewn passing a hill or elevated part, at which point a cutting or tunnel will be made; at *b*, a valley is crossed by a viaduct; and at *c* is an incline. Wherever the line crosses a road, a cross-section is made of this portion, in order that the engineer may be able to judge of the best method of laying out the approaches. When the actual construction of the line commences, the working-plan is the first operation to be attended to; in this, all the measurements, &c., are again taken, with greater accuracy than in the parliamentary plans. When the plan is completed, the exact line of the railway, within the limits prescribed by the Act, is determined upon, and marked out on the ground by stakes driven in at regular intervals of 66 or 100 feet, which are numbered for easy reference.

The centre line of the railway being thus ascertained, the working-section is then proceeded with, care being taken to observe every change in the undulations of the surface, and also the height at the stakes previously driven in, which are shewn on the section, and the observed levels marked thereon: when required by the nature of the ground, *cross-sections* are also taken.

The gradients are next decided on, care being taken so to adjust these that the cutting and embankment be as nearly as possible balanced, and the most judicious crossing of all roads and streams effected. The height of the embankments and depth of cuttings being now fixed, the engineer is in a position to set out the surface width, which varies according to the nature of the ground. Great judgment is required in laying down the line, in order to save extra bridges, cuttings, &c., which an injudicious curve might necessitate. In marking out the direction and levels of a tunnel, great care is requisite; the slightest inaccuracy will often involve a large additional expense, from the points of the gradients and direction not meeting with exactitude. In setting out the direction of the tunnel, a pole is fixed on the summit of the elevation through which the tunnel passes, from which the termini may be observed; other poles are put between these and the centre pole; and in the line of direction thus obtained, the shafts are sunk at the necessary distances, the depth of these being obtained from the section. Where a curve is employed for the line of the tunnel, it must be carefully set out on the surface of the ground. When the shafts are sunk, the direction in which the head-way is to be cut from the bottom of these, is ascertained by employing a compass, the direction being the same as that shewn by the indicated line on the surface of the ground.

In addition to the general plans and section here indicated, the engineer has other important drawings and documents to prepare; as designs for special constructions—bridges, viaducts, framing, tunnels, &c., the peculiarities of which may require the exercise of a high degree of engineering skill. Estimates also of the quantity of land required are to be prepared, and calculations made of the quantity of earth contained in the formation of embankments, and that taken from cuttings and tunnels. The majority of these operations are more or less facilitated by various publications, as Earth-work Tables, &c. Having thus glanced at the various points involved in the laying out of the line, we are now prepared to enter into the consideration of those connected with what may be termed the strictly constructive departments—the first of these forming the second division of our subject.

2. *Cuttings and Embankments.*—In carrying on cuttings, a considerable amount of forethought and care is necessary. Much depends upon the nature of the strata to be cut through. If the soil is loose, and much penetrated by springs, the expense of the undertaking is greatly increased. The slope of the sides depends upon the material. Rock is cut almost perpendicular; chalk generally admits of a small slope being used; while loose earth, or a stratification of clay and sand alternately, require to be finished with a much flatter slope, so that the sides may not slip in. In commencing a cutting, the coating of soil is first removed, and a gullet or channel cut, to admit of a set of temporary rails, on which the wagons containing the excavated material are run out to the embankment where it is to be deposited. As the cutting proceeds, the width is increased, to admit of the rails being laid along each side, thus allowing two sets of wagons to be filled at the same time. If the cutting is of large dimensions, *runs*, or sets of planks, are placed on the sides in different directions, along which the soil taken from various elevations is conveyed to the wagons. To prevent the water

accumulating—one of the greatest inconveniences attendant upon the operation—the cutting is commenced at the lower end, so that the water can be easily drained off and allowed to run away. As before stated, it is desirable to have a cutting in near proximity to the place where an embankment is required, and if it can be arranged to have the inclination from the cutting to the embankment, so that the wagons can run down by their own gravity, regulated by a break, a considerable saving in the expense of execution is effected. Wagons are constructed so as to deposit the earth either from their sides or ends. The latter are so formed—being freely supported on two rollers—that, on gaining the end of the embankment, their progress being suddenly checked, the inertia causes the body of the wagon to tilt up, and to shoot the earth over the end of the embankment, which is in this way gradually lengthened. The body of the wagon is prevented from leaving the frame by two catches, which take hold of the rollers. The embankments are run out the full breadth at once, the rails at the *tip* being spread out fan shape, so that wagons can be directed either to the sides or centre as may be required. The embankments are also in the first instance formed to a higher level than the permanent one, to admit of subsidence before the rails are finally adjusted. The finishing of cuttings is a matter of great importance. The slopes are generally covered with earth, and grass is allowed to grow, which binds the soil together, and prevents it being carried off by surface-water. They are in some cases faced with retaining-walls, which effects a considerable saving, and affords great facilities for draining. In some situations it is also necessary to form small drains of tiles or broken stones obliquely across the slopes of the cutting, and other drains are cut to intercept water flowing in from higher levels; effective drainage being a most important item in construction. To the want or inefficiency of draining, the failure of earthworks is found generally attributable.

In cuttings, the great point to be attended to is the avoidance of *slips*. After every care has been taken, and the railway fully completed, the sides have frequently fallen in, and stopped for a time the traffic of the line. As before stated, the amount of slope or inclination of the sides depends upon the material, each material having a tendency to remain at rest at a certain angle, which is termed the angle of repose. Generally, for every vertical foot of depth of cutting, a foot and a half of slope is allowed. In fig. 15, we give the sketch of a railway cutting: *a*, *a*, the lines of rail; *b*, the drain between; *c*, *c*, the side-drains; *d*, the sloping sides. In some cases it is necessary, to insure stability of the cutting, to build retaining-walls, as *c'*: the drainage-water from the side drains is led to the central drain, *b*, by small branch-drains. In many cases the central drain is dispensed with, and only side and branch drains formed.

The most remarkable application of science and engineering in dislodging a mass of material without the necessity of cutting, was the removal of a huge chalk-cliff on the line of the Dover Railway by blasting, the ignition of the powder being effected by means of galvanic batteries. A mass of material, which would have cost £10,000, and occupied twelve months in cutting, was thrown down in a few seconds at a cost of £7000.

Some idea of the magnitude of railway operations may be formed when we state the fact, that if the material excavated in the making of the London and Birmingham Railway was made into a bank a foot broad and a foot deep, it would go three times round the earth at the equator.

The slope of embankments is usually made equal to that of the cuttings, it being considered a rule of pretty general application, that the angle at which the cutting stands will suit for that of an embankment, constructed of the earth taken from the former. On completion of the embankment, the slopes are covered with soil, and sown with grass or clover seeds, the vegetation of which ultimately forms a turf, which tends greatly to keep the surface of the embankment in good repair. In some cases, the nature of the ground over which the embankment has to be carried renders its execution a matter of extreme difficulty; and the skill of the engineer is taxed to the utmost. The most important work of this kind ever executed was the Chat Moss embankment on the Manchester and Liverpool line, Mr Stephenson being the engineer. Other morasses—as the Stratford marshes, the Ashton and the Cockwood—have also called forth great skill on the part of the engineer. In the first mentioned of these cases, the ground was of so yielding a nature as not to allow even cattle to walk over it. The first operation was to thoroughly drain the moss, and thereafter to form the embankment by the light dried moss itself. At another portion, where the ground was of such a yielding nature that it absorbed an immense mass of material without result, Mr Stephenson adopted the plan of laying hurdles of wicker-work on the absorbed layer of dried moss; upon these hurdles, the gravel was placed to form the permanent way, wooden sleepers being employed to support the rails.

3. *Tunnels.*—It is considered a rule in railway engineering, that if a cutting is to be more than sixty feet deep, and no embankment is near to which the earth may be taken, it is cheaper to bore a tunnel than make the cutting.

The shape of the tunnel depends much upon the material through which it has to be formed; for a mobile soil, it is nearly a circle. In fig. 16, we give a

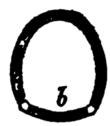

Fig. 16.

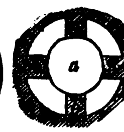

Fig. 17.

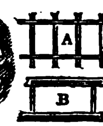

Fig. 18.

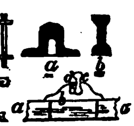

Fig. 19.

sketch of the usual form of a brick-lined tunnel; this is of an oval shape, the sides and top being described with arcs of circles, and the bottom an inverted arch. The usual width is about twenty-four feet, the height, from the crown of the arch to the level of the permanent way, from twenty-four to thirty feet. In order to ascertain the nature of the strata through which the tunnel has to pass—and from this to decide on the form of its section, the thickness of the retaining masonry, and to provide for such casualties as may happen in the construction of the work—trial borings are made, or shafts are sunk, which are afterwards used for the working-shafts. These shafts are generally at equal distances; and, within certain limits, the nearer they are, the quicker and cheaper is the tunnel constructed—the labour in excavating and removing the material increasing as the distance increases from the point of labour to the foot of the shaft. As shafts are, however, expensive, they may be too numerous, and their cost exceed the saving effected as above noted. The shafts are sunk to the depth of the crown of the intended arch as follows:—Where the strata are uniform, and not likely to be much intersected by springs of water, a circular excavation is made as deep as the strata will allow, and at the bottom of this, a *curb* or circular ring of timber is placed. The internal circle of the ring is equal to the diameter of the shaft, and its breadth a little greater than the thickness of the brick or stone lining to the shaft. On this curb the lining is constructed, and the earth well rammed in behind as the work progresses: this is an essential point. When the top section has been thus finished, the excavation of another section is proceeded with; which, however, requires care to prevent the unequal sinking of the

lining already built. The centre portion is at first excavated to the necessary depth, leaving a ring of earth to support the wall, as in fig. 17, where *a* is the central opening, *bb* the wall. Four recesses are cut, as at *bb*, into which *shores* or timber props are inserted, and carefully fastened to the under side of the curb, and to sole-plates at their feet, so as to support the curb and the wall resting on it. The excavation is then made to the full diameter, and a second curb laid down, on which the building is carried up to meet the curb above. On this being done, the props are removed, and the recesses which they occupy built up. The same process is repeated till the necessary depth is obtained. This is the simplest method of sinking shafts; in cases of unusual difficulty, other plans have to be adopted; frequently such treacherous material is to be passed through, that entirely new appliances are to be designed, but our space does not allow us to enter further into the subject. We proceed, therefore, to trace out the succeeding operations. As the excavation is proceeded with from the crown of the arch to a short distance below the bottom of the intended tunnel, the sides are carefully lined with timber, and every means taken to prevent all disturbance of the soil. The requisite shafts having been thus constructed, a *drift-way* is commenced, to join the two contiguous shafts. This is usually some five or six feet wide, and seven or eight high, and serves the purpose of draining the work—opening up the means of communication between the shafts—and allows the sides of the tunnel to be set off with greater accuracy. The drainage from the drift-way is collected at the bottom of the shafts, when it is necessary to pump it up to the surface. The drift-way being completed, the excavation for the full width of the tunnel is commenced on each side of the shaft, the earth removed being taken up to the surface through the working-shafts. As the excavation is made, the sides and top are carefully supported by timber *centering* and planks. The building should be commenced when about twenty feet are excavated, under ordinary circumstances; and as the sides of the arch are carried up, the timber lining at the back which supports the earth must be gradually removed, and any vacuity or space left behind well rammed up. The crown of the arch is turned on a centre similar to that used for bridges. On the excavations from adjoining shafts approaching each other, the greatest care is requisite to prevent the improper disturbance of the earth between their ends. When the tunnel has been finished on each side of a shaft, the timber lining should be removed, the ground excavated, the brickwork of the tunnel built and carefully bonded with that of the portion previously completed. For the purpose of admitting light, and freeing the tunnel from smoke, steam, &c., some of the shafts may be left open, which in this case are made of larger dimensions than simple working-shafts. The ends or *fronts* of the tunnel are faced with a retaining-wall, and frequently finished in an ornamental manner. The thickness of the brickwork of the arch is usually eighteen inches. Great care is requisite to prevent the accumulation of water behind the brickwork; a drain is generally laid along the centre of the invert *b*, fig. 16, to which other drains from the sides are led.

Tunnels passing through solid rock or chalk are left as excavated; but the strata through which some pass are so diversified, that brick-lining is frequently necessary. In no department of railway construction do difficulties so frequently arise as in tunnel-making; these call forth the utmost powers of the engineer, and seem at times destined to baffle his ingenuity and resources. Of remarkable tunnels may be mentioned the Box Tunnel, on the Great Western Railway; it is 9400 feet long, and 400 feet below the highest part of the hill through which it goes: thirteen shafts were required in its ventilation and construction. The longest tunnel in England is the Summit Tunnel, on the Sheffield and Manchester line, which is more than three miles long; it took six years to finish; the average depth of the shafts was 600 feet; nearly 160 tons of gunpowder were used in blasting, and 8,000,000 tons of water were pumped from it. The cost of constructing tunnels varies from £20 per yard in the easiest, to £100, and £150 or £160 for the most difficult strata.

4. *Bridges and Viaducts.*—Railway bridges of one arch are generally used to carry the railway over roads, canals, and short ravines; valleys and rivers are generally crossed by bridges containing a number of arches, which are termed viaducts. Where the bridge crosses a road, &c., at right angles, its construction is a matter of ease; where, however, the road, &c., to be crossed is oblique to the line of railway, a skew-bridge is used, in which the arch is oblique to the abutments. Natural and local difficulties have frequently necessitated the erection of bridges of a peculiar form, as the 'telescopic' drawbridge over the Avon, where the railway is placed upon a movable platform, which is made to pass over, or leave the water-way clear, as desired. But the most remarkable construction yet carried out is the Britannia Bridge, which crosses the Menai Strait. This, the most wonderful engineering project connected with railways, has been so frequently described, and its proper elucidation would take up so much space, that we have merely to state that it consists of two long tubes, one for the up, the other for the down lines, each tube forming a rectangular tunnel or square box of malleable iron, the sides, top, and bottom of which are composed of a series of cells. These tubes are supported on piers, one of which rises from a rock in the centre of the stream, to a height of 230 feet. The total length of each tube is 1492 feet, and they cost in their construction half a million.

Some of our railway viaducts are gigantic undertakings. The one over the Valley of the Dee, on the Shrewsbury and Chester line, is 150 feet above the level of the river, and is nearly the third of a mile in length. While stone or brick was almost invariably used in earlier constructions, timber alone, or timber combined with stone, or brick, is now adopted with success. A timber viaduct connects the Bricklayers' Arms station with the main line of the Brighton Railway. In Scotland, timber-trussed viaducts of great span have been introduced with economical results. The timber is preserved from the ravages of insects and from dry-rot by a chemical process. Of viaducts extending into, or crossing arms of the sea, a remarkable instance is afforded at Hull; it extends 1500 yards into the estuary. Some railways are almost wholly constructed on arches, as the Blackwall and Greenwich lines. The spaces below the arches are let out as warehouses, &c., and thus yield a revenue. A remarkable species of viaduct or bridge is met with at Newcastle-on-Tyne. Both railway and roadway are carried over the river by one structure, the latter being suspended from the great arches which carry the railway; the length of the carriage-road is 1330 feet, its height above the river is 80; the height of the railway is 102 feet.

5. *The Permanent Way.*—When the proper level has been attained throughout, the road is prepared to receive the rails by being *ballasted*, which consists in laying a stratum of broken stone, gravel, or chalk to the depth of fifteen to twenty-four inches. The rails are connected together by *chairs*, which formerly used to be fixed in square blocks of stones. Stone-blocks have been since discarded, and wood-sleepers are now almost universally adopted. There are two methods of laying wood-sleepers: one in which the timber supporting the rails is laid down in a continuous line, and connected together at intervals; the other, in which a series of timbers are laid transversely at certain distances from each other. The longitudinal bearing is that which has been chiefly used on the broad-gauge lines; the

rails being at once fastened on the timber, without the intervention of chairs. It is stated that the *bite* of the locomotive on the rails so laid is not so great as on the cross-sleepers. The latter plan is that which is chiefly adopted. The distance between the sleepers varies, according to the weight of the rails, from two and a half to four and a half feet. They are now made of larger size than formerly, and subjected to an antiseptic process before being laid down. In fig. 18, B shews the method of laying the longitudinal bearings, and A the cross-sleepers. In the longitudinal bearing, the form of rail is that known as the bridge-rail, as at *a*, fig. 19, which is fastened to the sleeper by nails or bolts passing through holes made in its lower flanges. Where cross-sleepers are used, the rails are supported by chairs; the sections of rails of this class are numerous. In fig. 19, *b* shews one in use on many railways; it is known as the 'double-T' rail. In fig. 19, at *c*, is a form of chair much used. The body of the chair, *b*, is of cast iron, and is fastened down to the sleepers, *a*, *a*, by wooden trenails, or iron spikes, passing through holes made in the sole of the chair. One side of the space into which the rail, *c*, is passed is curved, against which the rail rests, the other side, *d*, is flat; and into this space the compressed wedge or key, *d*, is firmly driven. These keys are generally of hard wood, previously steamed, and compressed in a hydraulic press. This treatment prevents them from shrinking in dry weather, and becoming loose.

In laying the rails, the exact width is accurately adjusted by using a gauge; and space is left between the ends of the rails to allow of their expansion. Drainage should also be attended to; for this purpose, open drains are generally cut across the ballasting at right angles to the line of rails.

The form of the rail has been a matter which has always claimed the attention of the engineer, and a variety of shapes and methods of manufacture have been introduced. Mr Peter Barlow's 'cast-iron chair and sleeper' system has been adopted with great success in two lines of railways. By it, he obtains a hard and rigid line, which he holds to be desirable. Mr Barlow's brother, W. H. Barlow, has introduced another method of permanent way, which he terms the 'broad-flanged wrought-iron rails.' This is coming largely into use, and seems likely to bring about a revolution in this department of railway engineering. As the capabilities of the railway system have been developed, the rails have been gradually increased in weight. At first, they were laid down of a weight of 35 pounds to the yard; this gradually increased to 50, 62, 72, till a weight of 85 pounds to the yard is now sometimes used.

As to the important point of the durability of the rails, it was stated in a report on the subject to the directors of the London and North-western Railway, that the average 'lifetime' of the rails was twenty years, after the expiry of which term the whole line would be required to be relaid. It has been calculated that one engine abrades no less than 2·2 pounds from the rails by passing over sixty miles, and each ton of load about an ounce and a half. The cost of a mile of permanent way may be set down at £2000 to £2400.

To meet the various exigencies of railway traffic, provision must be made to enable trains to be taken from one line of rails to another, or from the main line to *sidings*, or *vice versâ*. This is effected by *switches* and *turn-tables*. Where a switch is used, the rails of the siding are brought up to the main line; the ends of one rail of the latter and one of the former are made movable—these are called the *tongues* of the switch—and are brought to a narrow point, so that the wheels may pass without any shock from one line to the other. The points are kept in their proper position by a weight which is attached to the lever, this being moved as desired by the pointsman. On some railways, self-acting switches are used; these allow the carriages to pass from the main line to a siding, but not to return without the intervention of the pointsman. This prevents accidents from carriages being moved, by the wind or other causes, into the main line from a siding. In fig. 20, we give a diagram illustrative of the arrange-

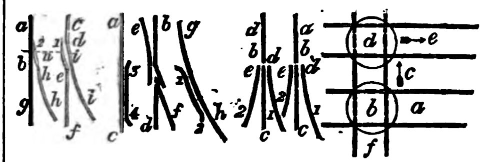

Fig. 20. Fig. 21. Fig. 22. Fig. 23.

ment of a siding, shewing the action of the switch. Let *abg* be the left-hand main-line rail, and *cd* the right-hand one; this is continued at *ef*. At this point, a portion of a rail, *e*1, is jointed, and is gradually tapered nearly to a point, this fitting into a notch made in the main rail *cd*. The right-hand rail of the siding is at *ii*; the left hand at *hh*. At the point *h*, corresponding to *e*, a tapered tongue, *h*2, is jointed, fitting into a notch in the rail *abg*. The two tongues of the switch are connected by a bar, *n*, which is moved by a handle at *b*. In the position in the diagram, the flange of the right-hand wheel will enter the space left between the end of the tongue, *e*1, and the rail *cd*, and will consequently leave the rail 1*ef*, and follow *cdii*; the other wheel will go on the rail *hh*, and the train will thus pass into the siding. The tongues of the switch are ordinarily kept in the position the reverse of this, by means of a weight attached to the end of the lever, as explained above. In order to prevent the flanges of the wheels striking against the point 5, where the main line and siding intersect, two guard-rails, 1 2, 3 4, are placed, as shewn in fig. 21, *ac*, *bd* being the main line, and *ef*, *gh* the siding-rails. In fig. 22, we give a sketch of another arrangement of switch: *a*, *d*, the main rails, with the tongues of the switch, *bb*; *ec* the continuation of the main line. When the switches *b*, *b* are in the position in the diagram, the train proceeds along the main line; by moving them till they coincide with *dd*, the train proceeds along the right-hand siding *d*1, *d*1; if moved to *ee*, the train proceeds along *e*2, *e*2. Where single carriages are to be moved from one line to another, a turn-table may be used. This is a circular platform, revolving on wheels or rollers beneath. It is provided with a set of rails, on which the carriage is placed; the table is then turned round, to make the rails correspond with those of another line as required. Thus, if a carriage is required to be taken from the line *ab* to the line *de*, fig. 23, it is passed on to the turn-table *f*, which is then wheeled round until the carriage is in the position shewn by the arrow at *c*. It is then moved along the cross-rail *bd*, to the turn-table *d*, where it is again wheeled till it assumes the position of the arrow *e*, where it can be moved along the line of rail *de*. Carriages can also by this contrivance be removed from any line, as *a* or *d*, to a cross-line, as *c*.

As these turn-tables are fixtures, a plan of moving carriages from one line to another, and capable of being used at various points, is required. This is known as a *traversing-table*, and is a low rectangular platform, on to which the carriage is moved, and thence transported to any point as desired, the whole being effected by simple mechanism. It is particularly useful at stations.

In thinly populated or agricultural districts, single-lined railways are likely to come into general use. On single lines, trains are allowed to pass each other by means of sidings, where there are two lines of rails connected with the main line by switches which are made self-acting, and are so adjusted that one train passes over the right, while the train approaching in the opposite direction takes the left set of rails.

In addition to the subjects above considered, it is

the duty of the railway engineer to devise the various arrangements necessary to work the line—as signal-stations, tanks, and apparatus to supply water and fuel to the engine, roofs of stations, &c.; for which we must refer the reader to works treating of railways more in detail. The management of railways, and their commercial and social aspects, are noticed in the paper on INLAND CONVEYANCE.

MARINE ENGINEERING.

This division of our subject comprises the construction of roadsteads, breakwaters, harbours, docks, and the protection of sea-coasts.

Roadsteads are of two classes—*land-locked*, and *open*. In the former, the anchorage is protected from the weather and the action of the deep-sea waves by projections of the land; in the latter, the anchorage is more or less unsafe, by being fully exposed to the ocean-swell and the winds, and consequently requires special construction, in order to lessen the danger. This is usually effected by laying down a breakwater, which may be defined as an artificial island, constructed by throwing huge blocks of stone into the sea, and allowing them to assume the position produced by the action of the waves. The waves, rolling in from the ocean, expend their force on this structure, so that the water in the inner side is comparatively still. The interior of the breakwater is filled in with smaller stones, the facing being made of the heaviest blocks, laid with as much care as is possible under the circumstances. Experience, however, has shewn that where the exposure is great, this rough facing should not be trusted to, but that a covering of heavy blocks, carefully adjusted to one another and set in hydraulic cement, is requisite to resist the action of the waves under the heaviest gales.

The most gigantic of all the works of this kind, and the first in priority of execution, is the breakwater at Cherbourg, in France, of which a section is given in fig. 24. This work is of extraordinary dimensions—in length, it is nearly 4120 yards. Up to the level of twenty feet below low-water mark, the breakwater is composed of small stones, and it is ascertained

Fig. 24.

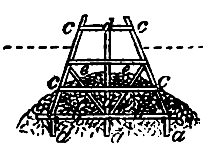

Fig. 25.

that the action of the waves up to this level is comparatively slight, inasmuch as the original outline of the mass has not been materially disturbed. Above this level, however, the waves exercise an enormous force, displacing, in heavy gales, blocks of the largest size, and gradually altering the outline presented to the sea, making it more and more flat every year. In 1829, it was considered necessary to crown the breakwater with a vertical wall. The top-surface was covered with large loose blocks, and the wall rests upon large blocks of *beton*, or artificial stone. The wall is constructed of heavy courses of granite ashlar, the interior being filled up with rubble. Another celebrated example of this kind of structure is the Plymouth breakwater, designed to shelter the sound which forms the entrance to the harbour of Plymouth and Devonport. The length of this is 1700 yards, the central part being 1000 yards, and the two arms, which make an angle of 135° with the centre, being 350 yards each. The width at the bottom is 133 yards, and at top 15. Part of the sea-face is paved with large stones set in hydraulic cement, from the top to the level of low-water at spring-tides. A light-house, 60 feet in height, is formed at one extremity. Experience has proved that the vertical wall in the Cherbourg breakwater is more effectual in maintaining still water at the land-side than the slope of the breakwater at Plymouth, although the former is much more liable to damage than the latter

What are termed *floating breakwaters* have been proposed at different times, but as yet, we know of no instance of their adoption on a large scale. The late Sir S. Bentham drew out a plan of such a breakwater for Plymouth, the distinguishing feature of which was the construction of prismatic floats of timber, securely moored across the entrance to the Sound. The floating breakwater of Captain Taylor consists of timber caissons or frameworks, fastened together by chains of a peculiar construction; and is recommended by the inventor on grounds of economy, quickness of erection, and, from its open character, preventing the deposition of silt, which a solid erection is likely to promote.

Harbours may be classed as natural, artificial, and composite—that is, partly formed by nature and partly by art. Any creek, sound, or estuary sufficiently deep and land-locked, constitutes a natural harbour for shelter; but for the purposes of commerce, quays, wharfs, and landings must be erected by man. When harbours wholly artificial are to be constructed, excavations have sometimes to be made, but more frequently piers and jetties are built forward into deep water, a certain amount of space enclosed, and breakwaters erected for its protection.

The harbour space is enclosed either by wooden piers or jetties, or stone-walls or dikes. A variety of circumstances have to be taken into account by the engineer before deciding upon the plan of the harbour: he must make himself acquainted with the prevailing currents and winds; the various soundings; and the likelihood there is of the harbour becoming silted up by deposits of shingle or sand brought up by certain currents. In laying down the plan, an important point is to afford the utmost possible facilities for vessels *entering* the port—the reason for this is obvious. The plan of the jetties varies according to circumstances, and to the opinion of the engineer; a usual form is to make the two jetties in curved lines, parallel to one another, the convex sides being in the direction of the currents which bring up deposits of sand or shingle. The opening at the outer end varies also according to local circumstances—it should rarely be less than 300 feet wide. It is usual to make one of the jetties longer than the other, as, nearly on every coast, there is some prevailing wind or current which will influence vessels entering the harbour.

In fig. 25 we give a diagram shewing the usual form of a wooden jetty: *a*, *a*, the piles driven into the ground to form the foundation; *b*, *b*, the cross-pieces; *c*, *c*, the inclined side-pieces; *dd*, the central upright; *e*, *e*, the struts. The upper part is finished with a strong plank flooring, with spaces between the planks to allow of the water passing through. To protect the piles as much as possible, stones or masses of concrete are thrown in at the sides; this filling in being carried up to the level of high spring-tides, where the situation is much exposed. The frames, as shewn in fig. 25, are placed at distances apart according to circumstances, usually from six to ten feet, and are connected together with longitudinal pieces. The great advantages possessed by wooden jetties are cheapness and rapidity of construction; exposed, however, as the timbers are to the ravages of sea-insects and to the action of the waves, they more frequently require repair than jetties constructed of stone. To prevent the ravages of the insects, various means are adopted, which our space will not allow us to notice. (See Practice of Architecture, No. 29.) Stone piers and quays form the most substantial structures; they consist in general of rough rubble, faced seaward with dressed blocks placed on edge, and built slopingly, so

as to present a gradual resistance to the impact of the waves, and finished harbourwards with stone coursings, so as to offer a concave or slightly bevelled wall to the sides of the vessels.

Fig. 26 gives a cross section of a stone-jetty, in which both faces, *c*, *d*, are constructed in coursed ashlar, the heart being filled up with rubble. In some

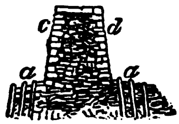

Fig. 26.

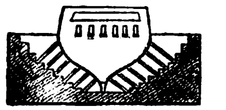

Fig. 27.

cases, it is necessary to protect the foundation with what is called an *apron*, consisting of piles and stones, as at *aa*. Where the sea-face, as *c*, is nearly vertical, the action of the waves is less dangerous than when a long slope is presented to them, as is the case when jetties are constructed after the manner of break-waters—that is, of loose rubble thrown together. In constructing a jetty such as that in fig. 26, the largest stones obtainable should be employed, and means taken to bind the various courses together; the upper surface or roadway being finished with stones carefully dowelled to each other, and so constructed as to throw off readily all water lodging upon it. Quay-walls require to be constructed with great care; to facilitate the discharge of the vessels which lie against them, the more vertical the face of the wall the better, although, for the purposes of stability, it should be inclined. The usual practice, to satisfy both those conditions, is to give a curved outline to both sides of the wall, the outer face being concave. The great difficulties to be overcome in these constructions are—the wet condition of the soil behind the walls, and the yielding bed of mud on which the foundations rest. To obviate the dangers arising from these sources, requires the exercise of great skill on the part of the civil engineer.

The prime objection to harbours enclosed by solid walls and breakwaters, is their liability to be obstructed by deposits of sand, shingle, and other marine silt. Rivers and sewers entering the harbour, the drifting action of the tides and waves, all tend to collect débris; and unless these natural forces be made to counteract each other, or extraneous sluicing and dredging operations be resorted to, both fairway and basin of the finest harbours will in time be rendered useless.

The method which has been generally resorted to for clearing harbours of silt, is the establishment of a powerful current at low-water, proceeding from an inner backwater reservoir capable of being regulated by sluices. This, however, is not found effectual, the silt being generally deposited at the point where the outer current meets that flowing from the harbour. Although the above contrivance is still used in most harbours to a certain extent, dredging-machines are also employed in scooping up, by the power of steam, the mud and shingle, which is emptied into boats, and carried out and deposited in deep water. Another remedy has been proposed—namely, to convert the action of the tides and waves into a sluicing power. This is to be effected by leaving arched openings at frequent intervals in the piers and quays, through which the waters would pass with a force sufficient to scour away every vestige of deposit. It is worthy of note that the ancient Romans adopted this plan on the shores of the Mediterranean.

Docks are inner basins formed in connection with harbours, where vessels may float whatever be the state of the tide in the outer basin, and are generally lined with stone, and provided with appropriate gates or sluices. They are usually described as *wet* to distinguish them from *dry docks*, afterwards referred to. Wet-docks are used for the purpose of loading and unloading; and as they can be completely isolated from other parts of the harbour, every facility is given for warehousing and for conducting the business of the Customs. The level of the water in the docks corresponds with high-water in the harbour or roadstead with which they communicate; consequently, at high-water, ships can enter and leave them, and, if necessary, at low-water they can be sluiced out and cleaned. In tidal rivers, where the range of the tide is great, it would be impossible to conduct a shipping business to any extent without wet-docks; and thus on the Mersey, for example, upwards of a hundred acres of dock, of unparalleled magnificence, have been constructed for the commerce of Liverpool and Birkenhead. The extensive shipping-trade carried on at Glasgow is an example of what may be done in a tidal river without docks, where the difference between high and low water is not so great as it is in the Mersey—although the want of wet-docks has been much felt and is now in course of being supplied.

The construction and operation of dock-locks are very similar to those used in canals, differing only in some points of detail. The gates are worked by means of chains and windlasses; and to enable them to work more freely, and to relieve the quoin post of much of the strain, the mitre post is provided with a metal roller, which runs on a quadrantal iron-way. The width of dock-gates must be such as to admit the largest vessels frequenting the port—docks to admit the large steamers now employed require wider gates than those for sailing-vessels.

Dry or graving docks are constructed so as to admit vessels for the purposes of repair. The sides of the dock are not vertical, but are made to conform somewhat to the contour of the vessel, by being built in a series of steps or set-offs. The dock-gates are constructed in a manner similar to those of the other docks; and on the ship entering at high-water, if the graving-dock opens into a wet-dock, the gates are closed, the water pumped out; and the ship resting on her keel on the bottom of the dock, is shored up and supported by timber, as shewn in fig. 27. By this arrangement, ample space is secured for the workmen carrying on the necessary repairs, and access easily obtained to any part of the contour of the vessel. After the vessel has been repaired, the tide is admitted, the gates are opened, and the vessel floated out. If the graving-docks communicate with the outer or tidal harbour, of course it is not necessary to pump out the water, but merely to close the gates at low-water, which exclude the rising tide.

What are termed *naval docks* are depôts fitted with all sorts of naval stores, and all the requisite machinery for ship-building. The principal naval docks of Great Britain are Portsmouth, Plymouth, Chatham, Sheerness, Woolwich, and Deptford. It is in these docks, and particularly in the first three, that ships-of-war are laid up in time of peace. Vessels can also be conveniently laid dry for repairs by Morton's patent slip, by which the vessel having been allowed to settle down upon a cradle, as the tide falls, is then dragged up an inclined plane by steam-power.

Protection of the Sea-coast.—This is usually effected in Holland, where the most gigantic of such constructions are to be met with, by erecting *dikes* of ordinary earth, of a trapezoidal form in their section. In many places, the top of the dike is little more than three feet above the level of the highest spring-tide. The outer slope, which inclines from three to twelve feet horizontal for one vertical, is finished in a variety of ways, all having the great object in view, of preventing the destructive action of the waves. One plan adopted for this purpose is to cover the face with straw thatch, firmly secured by timbers interlaced with wicker-work, the interstices being filled with stones. This covering is found to resist the action of the waves as well as of currents. Coasts are also protected by fortifying the shore with what are termed *groins*. These are low

erections, which are carried out from the beach in a direction perpendicular or oblique to it, and constructed in various ways, as by throwing up clay and protecting the faces with stones, or by driving piles in juxtaposition—the object being to arrest the current, and cause a settlement of the deposit held in suspension by the water. A very efficient coast-defence has been adopted at Havre, which consists of an embankment having a row of sheeting-piles, with an apron of loose rubble stones. In cases where the sea acts upon a high coast or cliff, and is gradually wearing it away, the only method to insure protection is to build a sea-wall, the face of which should be constructed of large blocks of stone in ashlar courses, well set in hydraulic cement, and the back filled in with concrete or rubble. Every precaution must be taken to prevent the pressure from behind forcing out the wall. The foundation may be protected by an apron of rubble stones at its base.

In carrying out marine works, the engineer will require to study carefully the action of the waves, currents, and the prevailing winds of the locality; the material available for his operations must also be the object of his investigations; nor must he forget that the action of the sea-water will materially influence the permanency of the mortar and cements, and even the stones themselves. This subject has long engaged the attention of engineers and chemists; for it is obvious that if the stones are liable to disintegration, or the mortar or cement rendered useless, it matters not how carefully in other points the works are designed.

On the subject of light-houses, see MARITIME CONVEYANCE.

River improvements have for their object either to deepen the water-way, so as to admit of free navigation, or to protect the banks, and prevent inundations of the surrounding land in time of floods. Space will only allow of our glancing very briefly at these subjects. To deepen the river, it is usually confined between banks, so as to contract the bed. In doing so, it is important to cause as little diversion as possible of the river from its original course. These banks are used to contract the bed at times when the water is low, and are covered with water during floods, as they are generally not higher than the mean level of the river. They may be constructed in a variety of ways—of blocks of stone, of fascines, or of concrete. Fascines are made by tying together a number of twigs placed parallel to one another by other twigs at intervals, according to the diameter.

To protect the ordinary river-banks, and prevent inundations, a variety of plans are adopted. Sometimes a rubble facing is employed; this only, however, where stone is easily obtained, as a large quantity is necessarily required. The banks may also be protected by fascines, as adopted in Holland. These are laid in courses, the small end towards the land, the large towards the water. Each course is set back a short distance from the preceding, forming by this means a regular slope or batter. The whole is finished as already described in the chapter on sea-coast improvements.

Where the action of the current is not very strong, banks are efficiently protected by slopes covered with turf; the smoother the face of these is, the better. The turf, of course, requires to be put on before the usual wet season, to allow of its being consolidated, and bound by vegetation. If any patches get broken, they should be repaired as soon as possible. The height of the banks must be determined by the rise of the river when flooded; and where artificial embankments are required, they should assume the form of long mounds, sloping gradually on both sides. Where a river makes an abrupt bend, the full force of the current sets in towards the concave side, gradually wearing away the bank, unless it is protected, which is generally done either by deflecting the current towards the convex side by the erection of a dike from the concave side, at right angles or obliquely to the current, or by means already described. On the Po, a series of vertical frames are erected, supporting an inclined plane of planks, which has been found effectual.

Where bars are formed by deposits of silt at the mouth of rivers, they may be removed by dredging-machines, or by increasing the force of the current, which is effected by longitudinal dikes in the way already explained. Should the river separate into different small channels at the mouth, dams should be thrown across them, with the exception of one, which should form the main channel; by thus increasing the force of the current, the bed will be kept free from silt. The subsidiary channels should be provided with sluices, so arranged as to freely admit the tide when it is flowing, but closing at the ebb; by this means, all the water will be forced to pass out by the main channel, causing a scour which will clear away any deposits or obstructions laid down by the action of the tides or sea-currents.

We now come to the important subject of the *Supply of Water to Towns*, and *their Drainage*. It is only of late years that the public attention has been directed to the great importance of securing a supply of water, not only for domestic and manufacturing purposes, but to facilitate the discharge of the sewage. Now, however, the subject obtains the full attention it merits, and the various constructions connected with it form one of the most important branches of civil engineering.

The modern methods of supplying towns with water may be divided into two classes: supply by gravitation, and by steam-power; to which may be added artesian wells, a mode of supply much advocated by some engineers, and in a few instances adopted where the circumstances are favourable.

As to the first method, the principle is sufficiently explained in the name. The source is generally at some distance from the town to be supplied, and at a considerable elevation above it. The water is in the first instance led into a large reservoir or a series of reservoirs near the source, the supply being obtained from one or more streams leading into the reservoir. From the large reservoir, the water is conducted through sluices or gates into large cast-iron pipes, which follow the sinuosities of the ground in the most direct line to the town to be supplied. Here it is either stored up in a large reservoir, placed at the highest point of the city, and thence distributed to the districts by means of smaller pipes; or the large town reservoir is dispensed with, and the cast-iron pipes continued into the principal districts, from which smaller pipes branch off as required. Thus, in the following diagram, if *a* represent a lake or reservoir situated in a mountainous district, and *b* a town separated by several

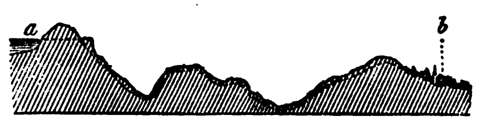

Fig. 28.

miles of irregular country, then on a pipe (indicated by the dotted line) being laid from *a* to *b*, the water will issue with a force sufficient to raise it nearly to the height of the original reservoir—a certain amount of force being lost through friction and atmospheric pressure. Several of our large, and many of our minor towns, are now supplied by this mode; the whole system consisting of the feeding-reservoir—which is generally situated in some hilly district—the line of pipes, with a few air-cocks for the escape of the accumulated air, branches or mains to lead the water into the different districts of the town, and ultimately small service-pipes and cisterns for the houses of the consumers. Wherever practicable, this is by far the most economical and certain method of supplying a town. Manchester, Glasgow, Greenock, Edinburgh, and numerous other places,

are all supplied on this principle. Where the elevation of the source is considerable, the pressure of water in the town pipes is so great as to force the water through jets fixed to them. To these, hose are attached, and the water is used for cleansing the pavements, or for extinguishing fire. Various substitutes have been proposed for cast-iron pipes, as earthenware and glass tubes, &c., but none of them are found so safe and economical as the iron. The iron pipes are made of dimensions suited to the quantity of water to be conveyed, varying from a few inches to three or four feet in diameter. They are joined together by the socket joint, or, as it is sometimes termed, the 'spigot and faucet joint'—the end of one being let into the socket formed at the extremity of the other, the joint being made water-tight by melted lead poured into it. In the improved water-pipes, the end going into the socket is carefully turned, and the interior of the pipe near the socket is bored, so as to produce a perfect joint, when it is lubricated with white-lead.

In designing water-works on the gravitation principle, a variety of points have to be taken into consideration. After deciding as to the situation of the collecting reservoirs—which is generally fixed upon from the presence of a stream or streams at a properly elevated source—the engineer must examine the ground, and ascertain the position of the various tributary streams which are likely to add to the quantity of water; these, with the main stream, must be carefully gauged, and the average daily supply ascertained. He should also consider the likelihood of obtaining supplies by carrying out the thorough drainage of the district, and by opening up of springs, calculating whether the probable expense of this will be repaid by the quantity of water obtained by it. To guide him in these calculations, the indications of the rain-gauge, extending over a comparatively long period, will be of essential service. The next point to be attended to is the construction of the reservoirs. The collecting-reservoirs are usually formed by throwing an embankment across a valley near the source of supply, while the distributing-reservoirs in the towns are generally constructed of masonry. The collecting-reservoirs should be of such capacity as to allow of water equal to some months' consumption to be stored up, and should have reference more to the 'maximum demand and the minimum supply than to the average of either.' The quantity allowed for the inhabitants' consumption may be estimated at twenty-five to thirty-two gallons per head per day; to this must be added the waste from evaporation and leakage. Where the population of a town is rapidly increasing, the reservoirs should be so planned as to admit of extension at a future time. The materials of which the reservoir walls, &c., are constructed should be well considered, as their influence on the stored-up water may be prejudicial. Great care must be taken in the construction of the retaining-walls—for notes on this point, see our remarks in the chapter on Marine Engineering. In some gravitation water-works the water is conveyed in conduits or culverts, as in the Croton water-works which supply New York. Conduits possess many advantages over pipes: the friction is less, and there is less chance of the water-way being choked up by the deposit of saline or chalky matters from the water—an accident which sometimes happens where spring-water is conveyed. Where conduits have to pass hills or rising-grounds, they must be taken through by means of a tunnel, which must be made of such size as to enable the workmen engaged in its construction to proceed with ease in their operations. Where valleys are to be crossed, one of two ways must be employed—conveying the conduit on arches, or forming a reservoir at one side of the valley, leading a pipe or siphon conduit down and along it, and up to another reservoir placed at the other side. Mr Rawlinson advocates the carrying of water across valleys by means of an elevated wrought-iron tube aqueduct—somewhat similar in plan to the aqueduct constructed by Telford for carrying the Chester canal across the Valley of the Dee, in which the water-way is formed of a cast-iron tank, which is now as sound and perfect as the day it was erected. A still cheaper method of conducting water from elevated sources, is by employing open channels, as done by the New River Company in London, and Mr Thom at Greenock. Grave objections may be made to this plan, especially in the neighbourhood of large towns, such as London—the loss from evaporation, the heating of the water, and consequent impetus given to the growth of weeds and insects, the positive contamination of the water through filth thrown into the channel, and the necessity of employing collecting-reservoirs and filter-beds in or near the town, may be noticed here as the most important of these.

In fig. 29 we give a section of the water-works carried

Fig. 29.

into execution at Kilmarnock on the same principle of arrangement as that adopted at the Gorbals Gravitation Water-works, Glasgow. The drawing exhibits the connection of the large reservoir with the self-acting sluices, filter, and pure-water basins. 'By means of the self-acting apparatus which has been adopted, the pure-water basins are kept at the same level, whether the draft at the town be great or small, by first operating on the conduit leading to the filters, and then upon the valve in the pipe leading through the embankment to the lower reservoir—thus making the whole works self-acting, without the intervention of manual labour.'

In all places where there is a deficiency of altitude to carry the water naturally to the highest parts of a town, there is no resource but in the employment of machinery. A steam-engine, or other agent, is applied to the working of pumps, which first draw the water from rivers or wells, and then force it through a train of pipes to all the different points of consumption. This mode is adopted in some of the densest centres of our population—as in London, Liverpool, Glasgow, Aberdeen, Perth, &c.: as, with us, fuel is cheap, and our steam-engines of unrivalled power and construction, pumping as a system is not without its advantages. The original water-works of Glasgow, which are compact and systematically constructed, may be taken as an illustration:—They are situated on the banks of the Clyde (which yields the supply) about two miles above the city, and occupy both sides of the river, the motive-power being on one side, and the aqueducts and filters on the other. The principal aqueduct or filter consists of an elliptical tunnel 7½ feet in diameter, and upwards of 600 yards in length, sunk ten feet lower than the level of low-water, in a bed of sand and gravel, through which the water filters naturally. This tunnel forms a curve parallel with the bed of the river, at about fifty feet from its margin. There are, besides, about eight acres of meadow-land, and nearly two of sand-filter, on which the water is raised by steam-power. The whole water produced by these filters is conveyed through a gravelly subsoil into the tunnel above mentioned. The water thus purified, is brought across the stream through four suction-pipes, laid in the bed of the river, and connected with the engines on the northern side. The water is conveyed into the city through the medium of four principal pipes or *mains*, as they are called, respectively of 14, 21, 25, and 36 inches diameter. As the ground on which Glasgow is built is of great variation of elevation, four intermediate stations or reservoirs have been formed, into which water is raised to the elevation requisite to supply the several districts, and no more; thus economising the power required to be exerted by the steam-engines, and furnishing

at the same time an abundant supply to those who occupy the highest houses.

In fig. 30 we give the section of the Trent Water-works at Nottingham, designed by the well-known engineer Mr Hawksley. 'The water is forced along a main of fifteen inches diameter through the centre of the town, and into a reservoir situated near the park, at an elevation of 135 feet, by a "double-powered" steam-engine of forty horse-power. This principal main supplies various district mains, which again feed the smaller pipes for the supply of the several streets. In these pipes are placed numerous fire-plugs.'

Fig. 30.

The cost of raising water by pumps worked by steam-power is given by Mr Hawksley. To transmit 500 gallons per second, two mains, sixty inches in diameter, will be requisite: to pump this water through pipes twenty-five miles long, into a reservoir 220 feet high, would take a power of 2500 horses, 500 horse-power of this being taken up in overcoming friction. The cost of twenty-five miles of mains would be £1,000,000; of the engines and machinery, £150,000; and of the tanks and reservoirs, £200,000. This calculation is made for London, supposing the water to be taken from the Thames above Windsor—which shews that a first investment of fifteen shillings, or ninepence a head of addition to the annual water-charge, would enable a 'constant supply of the purest soft water to be delivered at all hours, and into every story throughout London.' As a general statement, it may be said that by the use of steam-power from thirty to forty thousand pailfuls of water may be lifted fifty feet high for one shilling. The 'distribution' of the water to the various districts of the town to be supplied, is the same for pump as for gravitation works. Generally speaking, as the water is pumped up from rivers, much contaminating matter is mixed with it. To free it from this, large filtering-reservoirs are necessitated, into which the water is first conveyed—thereafter pumped into the city.

The principle of filtration, and its application to domestic purposes, will be explained in the paper on SUPPLY OF WATER. Filtration on the large scale is generally effected by passing the water through masses of sand or gravel. As the intercepted slime and sediment will in all cases tend to clog and fill up the pores of the filter, considerable ingenuity has been displayed in arranging the materials so as to retard this clogging, and in the construction of what are termed 'self-cleaning' filters. That invented and used by Mr Thom at Greenock, Paisley, Ayr, &c., is one of the most effective, and may be taken in illustration. In the accompanying transverse section, *a* is the conduit for supplying the water to the filter; *c*, a sluice for regulating the flow; *b*, a valve which admits the water above or below the filtering material at pleasure; *c*, a floor of perforated tiles, resting on a puddled basis; *f*, the filter, composed of layers of gravel and sand, gradually increasing in fineness towards the surface, the top layer consisting of fine sand and grained animal charcoal. The whole apparatus being completed, the water is allowed to enter the filter at the top, and passing through the different layers, it issues quite pure and free from taint. When the filter becomes foul, which is shewn by the decreased quality of water passing through, the valve *b* is reversed, and the current made to enter from below, carrying the particles of mud to the surface of the top layer, whence they can be readily removed. Maurra's self-cleansing sand-filter is also ingenious in construction, and efficient in operation, either in the large or small scale.

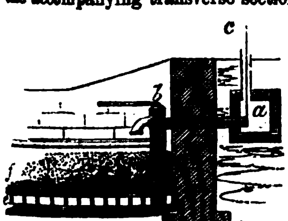

Fig. 31.

In the Gorbals Gravitation Water-works, already alluded to, the plan of filter is as follows:—There are three filtering-beds in duplicate, so that one set can be used while the other is cleaning. These are placed parallel to each other; the first contains a layer of 'sandstone shivers,' into which the water from the reservoir is admitted; flowing through the filtering material in this, the water passes up a hollow wall, which separates one bed from the other, and falls into the second filtering-bed, composed of gravel and sand; from thence through a second hollow wall, into the third filtering-bed of pure sand; and from thence into the pure water-basin, from which it is taken by a main to the town, a distance of nearly six miles. In fig. 32, we give a section of the plan of filter adopted at the Chelsea Water-works. 'A, A, depositing-reservoirs, capable of containing four days' supply; C, C,' inverts formed of open brickwork in cement, used for holding the deposit which is swept into them, and afterwards flushed out with water; B, the filter-bed, shewing the filtering substances, consisting of—1*st*, Coarse gravel, about one foot deep; 2*d*, A stratum of rough screened gravel, nine inches deep; 3*d*, Fine screened gravel, six inches deep; 4*th*, Fine gravel, nine inches; 5*th*, Fine washed gray river-sand, about three feet six inches deep. The water is gradually drawn from the depositing-reservoir on to the surface of the sand, and is allowed to percolate through tunnels formed by bricks with open joints and cement. These lead to other tunnels, which are made of close brick, and lead into the pump-well of the engine.'

Fig. 32.

The most recent improvement or novelty in public water-works is the application of Dr Clark's principle of purification (see SUPPLY OF WATER), which has been adopted by Mr Homersham at the Plumstead, Woolwich, and Charlton Water-works. The quantity of water softened at these works amounts to 600,000 gallons per day. The details connected with the distribution of water, and what may be called the social and domestic features of the question, will be found in the number above referred to, where also is given a description of the principles on which *Artesian* wells are constructed. Space will not allow us to enter into the details of the operations practised; for a description of these, we refer our readers to larger works, under the head Boring of Wells.

The removal of the drainage matters from the neighbourhood of our dwellings is effected by a system of sewers and drains; the former are underground channels of large dimensions, following the line of streets; while the latter are of smaller size, and connect the houses with the central sewer. A well-sewered and drained street, with houses on both sides, resembles in disposition a part of the human frame—the sewer representing the backbone, the drains the ribs. In the present article, we shall glance briefly at that portion of town-drainage to which the attention of the civil engineer is usually directed—namely, the laying down of the main sewers, and the arrangement and construction of their outfalls—leaving those points connected with the house-drains, and which usually fall to the care of the architect and builder, to be discussed in the number on the SUPPLY OF WATER—BATHS, &c.

In commencing the drainage of a town, the first point to be attended to is the outfall or place of final deposit of the drainage matters. Generally, the point chosen is the river which is in the vicinity of most of our towns; the public ideas are, however, becoming much modified on this point; and in view not only of the unhealthiness caused by the practice of polluting our streams, but of the pecuniary loss the community sustains by

throwing away that which is exceedingly valuable for agricultural purposes as a manure, many plans are now being proposed for storing up and treating the sewage matters of towns so as to yield a good manure in the solid form, or to lead it at once in the liquid form to the fields to which it is to be applied (see Irrigation, in AGRICULTURE). The plans for converting the sewage into solid manure are, however, only in contemplation, and it yet remains for the civil engineer to inaugurate successfully and economically a plan of treatment more consistent with sound reason than the one we now so universally adopt. The plan of liquid irrigation has long been adopted with a portion of the drainage of Edinburgh, where extensive meadows in the neighbourhood of the city have been treated in this manner, which has increased the productive powers of the soil to such an extent, that the crops of grass raised upon some of the best portions are annually let at a rental of from £40 to £45 per acre. The whole outlay is the expense of attending to the water-courses, and flooding the surface with the sewage matter at proper intervals, which amounts to a very small sum indeed, compared with the annual returns.

Where the river into which the sewers discharge is a tidal one, the engineer must be careful to arrange the size and position of the outlets so that space may be left for the accumulation of the sewage at times when the tide keeps back the usual flow. Every care must also be taken to make the sewers strong at these points, to resist the extra pressure to which they may be subjected.

The other points claiming the attention of the engineer are the shape, size, and inclination of the sewers. As regards the former, theory, as well as experience, shews that the circular form is the best calculated to assist the flow of the sewage, and prevent deposition of the contained matter. The 'egg-shaped sewer' is allowed on all hands to be the most efficient. In the first place, it is stronger than either the common square conduit with flagged top, or the upright-sided conduit with arched top and bevelled bottom. If the arch-stones are well formed and jointed, no weight or side-pressure can break it down; and if the ground is soft and yielding, the arched structure sinks as a whole. Again, when formed of two rings or courses, as shewn in the section, it is quite impervious either to moisture or effluvia, and requires less concreting and puddling than any other form. It is stated by Mr Roe, whose name is well known in connection with this subject, that with the same flow of water, the liability of the egg-shaped sewer to accumulate solid deposits is diminished one-half, compared with the old upright-sided and flat-bottomed conduit. Lastly, as the oval sewer combines the greatest strength with the smallest consumption of material, a very considerable saving is effected in construction, amounting from two to five shillings per lineal foot over the ordinary upright sewers with footing. Mr Williams has shewn that the saving

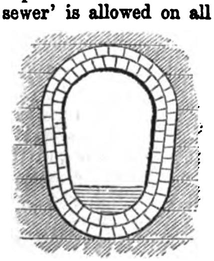

Fig. 33.

in the Westminster district by the construction of the egg-shaped instead of the upright-sided, in ten years, would have been upwards of £66,000.

Where street-sewers are required of small size, egg-shaped earthenware tubes are now used instead of brickwork. In laying these, great care should be taken to bed them well in clay puddling, and to have means here and there to ascertain the state of their interior. In all cases, they should be made very strong, as broken tubes, amounting to a large percentage, are generally found in drainage-works. A plan adopted at Croydon is well adapted to prevent this breakage; it consists in turning a brick arch, half-brick thick over the tubes, which saves them from the superincumbent pressure. The plan adopted by the Romans, of laying the pipes in a bed of pounded brick and mortar, is worthy of imitation. In the remains of some drain-pipes discovered at Zurich, the pipes were found so firmly bedded that pipes and bed formed one mass. All junctions of the house-drains with the sewers should be made of a circular form, never at right angles; because in the latter case, the meeting of the currents produce an eddy which tends to deposit solid matter, creates obstructions in the sewer, and involves considerable expense, as the pavement has frequently to be broken up and relaid, and this independent of the annoyance to the public through the blocking up of the thoroughfare by one of the most disgusting operations. Science at once points out the remedy, by directing the entering channel with a sweep or curve, as shewn in the accompanying diagram.

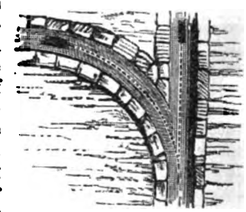

Fig. 34.

In determining the size of the main sewers, the engineer must be guided by the discharge from the houses of the district, so that when the maximum quantity passes through them, it will not fill the sewers more than half full. To the discharge of the sewage-waters of the houses, must be added the waste-water of manufactories; and special note must be taken of the average fall of rain, to allow for the 'storm-waters' of heavy showers. When our town-sewage is used for manure, the rain-fall will be carried from our streets to the river through special drains.

But while every care is taken to obtain a size of sewer well apportioned to the sewage matter which it has to convey, it is of essential importance rather to make it too large than to run into the opposite extreme, and make it too small. A neglect of this precaution may be attended with lamentable results. An investigation into the fever which numbered so many victims a year or two ago at Croydon, Kent, proved that much of the poisonous effluvia which contaminated the atmosphere proceeded from choked-up and broken pipe-sewers, which had been laid down of too small dimensions, and without any provision for ascertaining their condition. The rate of inclination of sewers may be made at one foot of vertical fall for every 100 of horizontal length; it may even be less than this, but should never fall short of 1 foot in 200.

INLAND CONVEYANCE.

THE artificial conveyance of person and property from one locality to another may be treated under two great heads—*Inland* and *Maritime*. To these, science may in time add a third—namely, *Aërial;* but as yet, all the schemes and experiments in this department have been without any available result. Confining our remarks, therefore, to what is real and practicable—roads, rivers, canals, and railways may be regarded as the main channels of inland transport; and the construction of these channels, in so far as artificial, having been discussed in the number on CIVIL ENGINEERING, it remains here to consider the subject in its social and economic aspect, and advert briefly to the history and management of the various modes of conveyance, and their more interesting features as commercial speculations. The consideration of ocean transport is reserved for a subsequent number. As a fitting introduction to our present subject, both in point of information and interest, we may briefly advert to the modes of conveyance adopted by nations but little advanced in the arts of civilisation.

PRIMITIVE MODES OF CONVEYANCE.

The means adopted in early times for artificial transport were, as may be supposed, of the rudest kind, as is still the case in those countries which are little advanced in the useful arts. The most degrading species of conveyance that seems to have been practised, was the employment of human labour in bearing litters or palanquins, specimens of which, on a scale of barbarous splendour, are now seen in India, Burmah, and China.

The first and most obvious improvement in modes of transport was the substitution of brute for human labour; and it is reasonable to conclude that the value of this practice could not have been long in being pressed on the attention of mankind. We find the term 'beasts of burden' used in the most ancient records, the animals meant being the ass, the horse, and the camel. No trace, however, exists of the progress from *burden* to *draught*, though it also must have taken place at a very early period. The ass and horse are equally adapted for carrying or drawing, but the camel exerts its power only by carrying; draught alone is suitable for the reindeer and ox, the backs of these animals being unfit by nature for burden.

Burden.

From the earliest times, the camel, in its two varieties of camel and dromedary—respectively two-hunched and one-hunched—has been employed in the sandy regions of Asia as a beast of burden; and without its invaluable services in this respect, these countries could scarcely have been habitable. In ancient times, it formed the engine of carriage among the merchants of Arabia, and conveyed the products of India across the deserts to the populous and wealthy land of Egypt.

The camel is expressly suited by nature for inhabiting and traversing sandy and parched deserts, in which there are places of rest and refreshment only at wide intervals. 'It is the most temperate of all animals,' says Goldsmith, 'and can continue to travel several days without drinking. In those vast deserts, where the earth is everywhere dry and sandy—where there are neither birds nor beasts, neither insects nor vegetables—where nothing is to be seen but hills of sand and heaps of bones—there the camel travels, posting forward, without requiring either drink or pasture, and is often found six or seven days without any sustenance whatsoever. Its feet are formed for travelling upon sand, and utterly unfit for moist or marshy places; the inhabitants, therefore, find a most useful assistant in this animal, where no other could subsist, and by its means cross those deserts with safety which would be impassable by any other method of conveyance.

'Camels are easily instructed in the methods of taking up and supporting their burdens; their legs, a few days after they are produced, are bent under their belly; they are in this manner loaded, and taught to rise; their burden is every day thus increased, by insensible degrees, till the animal is capable of supporting a weight adequate to its strength. The same care is taken in making them patient of hunger and thirst: while other animals receive their food at stated times, the camel is restrained for days together, and these intervals of famine are increased in proportion as the animal seems capable of sustaining them. By this method of education, they live five or six days without food or water; and their stomach is formed most admirably by nature to fit them for long abstinence. Besides the four stomachs which all animals have that chew the cud—and the camel is of the number—it has a fifth stomach, which serves as a reservoir to hold a greater quantity of water than the animal has an immediate occasion for. It is of sufficient capacity to contain a large quantity of water, where the fluid remains without corrupting, or without being adulterated by the other aliments. When the camel finds itself pressed with thirst, it has here an easy resource for quenching it: it throws up a quantity of this water, by a simple contraction of the muscles, into the other stomachs, and this serves to macerate its dry and simple food.

'In Turkey, Persia, Arabia, Barbary, and Egypt, the whole commerce is carried on by means of camels; and no carriage is more speedy or less expensive in these countries. Merchants and travellers unite themselves into a body, furnished with camels, to secure themselves from the insults of the robbers that infest the countries in which they live. This assemblage is called a *caravan*, in which the numbers are sometimes known to amount to above 10,000, and the number of camels is often greater than that of the men. Each of these animals is loaded according to his strength, and he is so sensible of it himself, that when his burden is too great, he remains still upon his belly, refusing to rise till his burden be lessened or taken away. In general, the larger camels are capable of carrying 1000 pounds' weight, and sometimes 1200; the dromedary from 600 to 700. In these trading journeys, they travel but slowly; their stages are generally regulated, and they seldom go above thirty, or at most about thirty-five miles a day. Every evening, when they arrive at a stage, which is usually some spot of verdure where water and shrubs are in plenty, they are permitted to feed at liberty; they are then seen to eat as much in an hour as will supply them for twenty-four. They seem to prefer the coarsest weeds to the softest pasture—the thistle, the nettle, the cassia, and other prickly vegetables are their favourite food; but their drivers take care to supply them with a kind of paste composition, which serves as a more permanent nourishment. As these animals have often gone the same track, they are said to know their way precisely, and to pursue their passage when their guides are utterly astray. When they come within a few miles of their baiting-place in the evening, they sagaciously scent it at a distance, and increasing their speed, are often seen to trot with vivacity to their stage.

'The patience of this animal is most extraordinary;

and it is probable that its sufferings are great, for when it is loaded, it sends forth most lamentable cries, but never offers to resist the tyrant that oppresses it. At the slightest sign, it bends its knees, and lies upon its belly, suffering itself to be loaded in this position: by this practice, the burden is more easily laid upon it than if lifted up while standing. At another sign, it rises with its load, and the driver getting upon its back, between the two panniers—which, like hampers, are placed upon each side—he encourages the camel to proceed with his voice and with a song. In this manner the creature proceeds contentedly forward, with a slow uneasy walk of about four miles an hour, and when it comes to its stage, lies down to be unloaded.'

From Major Skinner's account of his *Journey to India*, in the course of which he travelled twenty days with a numerous caravan from Damascus to Bagdad, we have the following lively picture of the mode of conveyance by camels:

'I must give a description of our equipage, now that we are fairly launched on the great waste. I ride a white camel, with my saddle-bags under me, and a pair of water-skins, quite full, beneath them: over the saddle is my bed. A thick cherry-stick, with a cross at the end of it, serves to guide the animal: a gentle tap on the side of his neck sends him to the left, and one on the opposite makes him turn back again to the right: a knock on the back of his head stops him, and a few taps between the ears bring him to his knees, if accompanied by a guttural sound, resembling, as the Arabs say, the pronunciation of their letter *sche*. To make him move quickly, it is necessary to prick him with the point of the stick.

'We passed over a perfect level this morning, strewed with flowers and thick with pasture for the camels, where we are now resting. It is not usual here, as in many parts of the East, for the camels to wind in long strings, one after the other. Our numbers, amounting to 1500, are scattered over the surface in all directions, as far as the eye can trace. In travelling, the sheiks, or chiefs of the caravan, attended by the military part of their equipage, mounted on dromedaries, move in advance, while the loaded camels follow at some distance, in parallel masses, opening out, or changing the form, as the grass renders it necessary. They fall so naturally into military figures, that it is difficult to conceive their doing it without direction. We have several tents in the caravan. They are pitched so as to permit the camels belonging to each to lie in the intervals, where they are placed in *squads* for the night. They are by no means agreeable neighbours; for although they are not able to move from their place, they make a most unpleasant gurgling noise.

'The rate at which a loaded camel travels is estimated at two and a half miles an hour by almost every traveller. Our caravan has not, I think, exceeded this; but the variety of its movements has been very tiresome. There is so strong a resemblance to a voyage at sea in a passage across the desert, that I cannot divest myself of the belief that the moving mass is but a collection of small vessels, carried into a heap by the tide. Every man is ready with his stick to fend off the animal that approaches him: one push separates the camels, as it would separate a couple of boats; and they move away, quite unconscious of the circumstance, till another movement swings them together again.'

Turning to the new world, we find, from the remotest period to which the Peruvian records extend, that the aborigines not only used the llama and alpaca for food and clothing, but also employed them in their military and domestic service, as the Arabs do the camel. The llama was principally destined to carry burdens, although, compared with the Asiatic drudge, the difference in size and strength is considerable. Its load, according to Mr Walton, never exceeded 150 pounds, with which it was not required to travel more than three leagues per day; whereas in the working part of the twenty-four hours, the camel journeys double that distance with 800 pounds or more upon his back. For this difference the Peruvians made up in the greater number of their beasts of burden, one drove sometimes exceeding 500 head, whose subsistence on the road was entirely left to chance. Neither whip nor goad was used to urge them on: one llama, older and more experienced than the rest, led the way, the others following irregularly but quietly after. Owing to its docility and knowledge of its keeper, this animal evidently requires less training than the camel. It needs no rein—not even a packsaddle—so long as the panniers or packages are well poised.

We need scarcely advert to the fact, that wherever civilisation has made any progress, the horse, the ass, and their hybrid the mule, have been used as beasts of burden—that is to say, in those countries which form their natural habitats. At what period the horse was first subjected to the purposes of man, we have no authentic record. He is mentioned by the oldest writers, and it is probable that his domestication was nearly coeval with the earliest state of society. Trimmed and decorated chargers appear on Egyptian monuments more than four thousand years old; and on sculptures equally, if not more ancient, along the banks of the Euphrates. One of the oldest books of Scripture contains the most powerful description of the war-horse; Joseph gave the Egyptians bread in exchange for horses; and the people of Israel are said to have gone out under Joshua against hosts armed with 'horses and chariots very many.' At a later date, Solomon obtained horses 'out of Egypt, and out of all lands,' and had 'four thousand stalls for horses and chariots, and twelve thousand horsemen.' Thus we find that in the plains of the Euphrates, Nile, and Jordan, the horse was early the associate of man, bearing him with rapidity from place to place, and aiding in the carnage and tumult of battle. He does not appear, however, to have been employed in the more useful arts of agriculture and commerce; these supposed drudgeries being imposed on the more patient ox, ass, and camel. Even in refined Greece and Rome, he was merely yoked to the war-chariot, placed under the saddle of the soldier, or trained for the race-course. As civilisation spread westward over Europe, the demands upon the strength and endurance of the horse were multiplied, and in time he was called upon to lend his shoulder indiscriminately to the carriage and wagon, to the mill, plough, and other implements of husbandry. It is in this servant-of-all-work capacity that we must now regard him; and certainly a more docile, steady, and willing assistant it is impossible to find. For burden, the ass perhaps is more steady and enduring; but both are surpassed by the mule, which in Spain, South America, Mexico, and other countries destitute of good roads, affords one of the most available modes of commercial transport. Headed by one of superior sagacity, they move in long cavalcades, like the camel and llama, and with their gay caparisons, tinkling bells, and jauntily-dressed drivers, form a very picturesque object in the landscape.

Another primitive mode of carriage, and the last which we shall mention, is the employment of the huge and unwieldy but powerful elephant. At what time this animal was first subjugated, and trained to take part in the court and military equipage of the East, we have no means of knowing. His form appears on the most ancient Hindoo sculptures; he figures in their mythology; and he is spoken of with pride and veneration in their earliest records. In that fertile and luxurious region, he had been trained for centuries before the names of Greece and Rome were known, and even long before the people of Western Asia had passed from the primitive or pastoral condition. It was to Alexander the Conqueror that the western world

was first indebted for the elephant; he it was that made the sports of Persia and India familiar to the Greeks and Macedonians. The acquisition of the war-elephant gave new pomp and splendour to his squadrons, and his example was followed by degrees by other nations. In time, the Egyptians, Carthaginians, Romans, all made use of elephants, both to assist in the march, by carrying enormous loads of baggage, and to join the ranks, mounted by numbers of archers and spearmen, as here represented.

Since the introduction of firearms and artillery, the war-elephant has been greatly abandoned even in the East, and is now chiefly used in carrying baggage, in doing other heavy work, and, above all, in adding to the 'pomp and circumstance' of Oriental authority. The present employment of the elephant in India, according to Von Orlich and other recent writers, is exceedingly varied—from the piling of firewood and the drawing of water, to the dragging of artillery and the carriage of royalty. When placed under the *howdah*—a covered seat for persons of rank—his back is protected by a thickly stuffed hair-cushion, over which is spread an ornamental covering. The howdah is made to contain two persons, and this is the amount of the travelling elephant's burden. The driver sits on his neck, immediately behind his ears, and guides him with an iron prong; and he is in general so docile, as to kneel for the parties to mount him. His great use, however, is as a beast of burden in a country where there are few or no roads; and since an ordinary elephant will carry as much as five camels, we can readily perceive his value in marching not only with the commanders and sick, but with the tents and furniture. He is equally serviceable as a beast of draught, pulling with ease what it would take ten horses to move; and it is for this reason that the Indian army have yoked him to their heavy artillery. Another power which the animal possesses, and one which is unknown to the horse or ox, is that of pushing; and if his forehead be protected by a pad, he will push forward weights which perhaps he could not draw. These, and many other duties, the elephant performs willingly, and, if gently treated and well fed, with a regularity of disposition which seems almost mechanical.

Draught.

The draught of the reindeer is employed in Lapland as the chief means of artificial locomotion, and is always exerted on a species of sledge, which, by its form, is suitable for gliding easily over the frozen ground or snow. The shape of the sledge somewhat resembles a small boat with a sharp prow, and flat in the rear, against which the inmate of the vehicle rests. The traveller is swathed in his carriage like an infant in a cradle, with a stick in his hand to steer the vessel, and disengage it from pieces of rock or stumps of tree that may happen to obstruct the route. He must also balance the sledge with his body, otherwise he will be in danger of being overturned. The traces by which this carriage is fastened to the reindeer are fixed to a collar about the animal's neck, and run down over the breast, between the fore and hind legs, to be connected with the prow of the sledge; the reins, managed by the traveller, are tied to the horns; and the trappings are usually furnished with little bells, the sound of which is agreeable to the animal. With this draught, the reindeer, if pressed, will travel from sixty to eighty miles in a day; but more frequently he does not travel more than forty or fifty, which is a good day's journey. Before he sets out, the Laplander whispers in his ear the way he has to go, and the place at which he has to halt, firmly persuaded that the beast understands his meaning. In the beginning of winter, the Laplanders strew fir-boughs to mark the most frequented paths; and the successive layers of fresh snow being pressed down by the sleighs, a firm causeway of snow comes to be formed, which is the more smooth if the surface has felt a partial thaw, and been crusted by a subsequent frost. It requires great caution to follow these tracks; for if the carriage deviates to the right or left, the traveller is plunged into an abyss of snow. In less frequented parts, where there is no such beaten road, the Laplander directs his course by certain marks made on the trees.

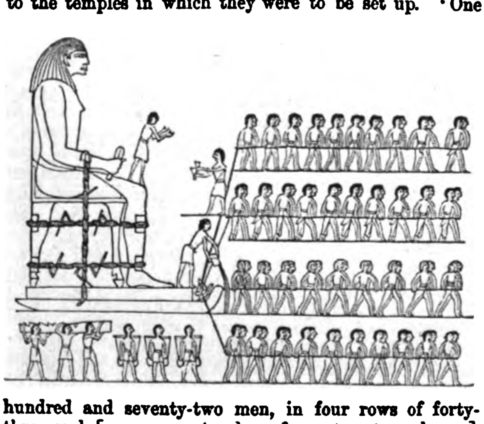
Among the Kamtschatdales, Esquimaux, and other northern tribes, a peculiar variety of dog is almost universally employed as a beast of draught, and occasionally as one of burden. These animals are trained to draw the rude sledges that the Esquimaux, for example, are able to construct, which are about five feet long and two wide. The runners are generally made of pieces of wood and bone lashed together, with the interstices stuffed with moss, and the whole secured by a coating of ice, which is readily produced by the severity of the climate. The runner is shod with a plate of hard bone, and water is poured over this, to form another coating of ice, which is renewed as often as it is worn off—a mode of shoeing which serves very well for nearly eight months out of the twelve. The dogs are harnessed by a collar, and a single trace running over their backs. They are not tied to each other, but each one is attached separately to the sledge, and at unequal distances, some even at twenty feet. The most docile dog is the leader, and his is the longest trace. A good leader is very attentive to the words of the conductor, and looks back over his shoulder with great earnestness to catch the word of command. Ten dogs make a full team, and will draw a sledge twelve miles an hour; and nine of them have been known to draw 1611 pounds a mile in nine minutes. Three dogs drew Captain Lyon, in a sledge weighing 100 pounds, a mile in six minutes. On a good surface, six or seven dogs will perform in a day a journey of sixty miles, with nearly 1000 pounds to draw. When there is no snow, the dogs are sometimes made to carry burdens in a kind of panniers, and one will travel thus with twenty-five pounds.

In Russia, and also in Canada, sleighs are used in winter for conveyance from place to place, the beast of draught being the horse. As the roads in many parts of Canada are very unsuitable for any species of travelling, it happens that sleighing over the hardened surface of the snow in winter is by far the best mode of communication in that country. It is almost unnecessary to add, that the sledge, which is the rudest kind of carriage for draught, has disappeared in all countries considerably advanced in improvement.

From the rude sledge, drawn with an incalculable degree of labour over the rough ground, the next important step in mechanical construction is to apply wheels, for the purpose of lessening the friction of the moving body. The first application of wheels to carriages is

beyond the reach of record. Wagons are spoken of in the book of Genesis, from which it may be inferred that a knowledge of wheels was common in a very early age. It is further known that the making of wheels formed a distinct trade among the citizens of Thebes in ancient Egypt, three or four thousand years ago. The most elegant of the Egyptian carriages was a kind of gig, or light open chariot, on two wheels, called the *plaustrum*, which is thus described by Mr Wilkinson in his work on the *Manners and Customs of the Ancient Egyptians:* 'The plaustrum was very similar to the war-chariot and the curricle, but the sides appear to have been closed, and it was drawn by a pair of oxen instead of horses. The harness was much the same, and the wheels had six spokes. In a journey, it was occasionally furnished with a sort of umbrella, fixed upon a rod rising from the centre or back of the car; the reins were the same as those used for horses, and apparently furnished with a bit; and besides the driver, a groom or runner sometimes attended on foot, at the head of the animals, perhaps feeding them as they went. The annexed engraving represents an Ethiopian princess, who is on her journey through Upper Egypt to Thebes, where the court then resided.'

From the researches of the same authority, we are enabled to form some estimate of the enormous trouble incurred by the ancient Egyptians in the transport of the heavy stones which they employed in building their temples. Some of these blocks weighed three or four thousand tons, and were usually conveyed from the quarries from which they were cut in flat-bottomed boats on canals made for the purpose. Occasionally, however, when this mode of transport was unsuitable, the stone was drawn on sledges, perhaps some hundreds of miles, by oxen, or by human labour. The accompanying wood-cut represents, in an abridged form, the mode of conveying colossal figures in stone from the quarries to the temples in which they were to be set up. 'One



hundred and seventy-two men, in four rows of forty-three each [we represent only as far as twenty each row], pull the ropes attached to the front of the sledge; and a liquid, probably grease, is poured from a vase by a person standing on the pedestal of the statue, in order to facilitate its progress as it slides over the ground, which was probably covered with a bed of planks, though they are not indicated in the painting. Some of the persons employed in this laborious duty appear to be Egyptians, the others are foreign slaves, who are clad in the costume of their country. Below are persons carrying vases of the liquid, or perhaps water, for the use of the workmen, and some implements connected with the transport of the statue, followed by taskmasters with their wands of office [but which we have not had space to include]. On the knee of the figure stands a man, who claps his hands to the measured cadence of a song, to mark the time, and insure their simultaneous draught. The height of the statue appears to have been about twenty-four feet, including the pedestal. It was bound to the sledge by ropes, which were tightened by means of pegs inserted between them, and twisted round until completely braced; and to prevent injury from the friction of the ropes upon the stone, a compress of leather or other substance was introduced at the part where they touched the statue.' Besides the great number of persons employed in drawing these huge blocks, it was customary for a band of some hundreds of soldiers to attend, perhaps for the purpose of overawing the slaves, and compelling obedience in their odious task. A more degrading means of mechanical conveyance, it would be impossible to represent.

TRAVELLING IN PAST TIMES IN BRITAIN.

The modes of travelling and conveyance in Britain were of a comparatively rude and primitive kind till the latter part of the seventeenth century; and anything like comfortable and quick travelling cannot be said to have been known till a century later, when mail-coaching was introduced. In old times, people of a humble rank travelled only on foot, and those of a higher station on horseback. Noblemen and gentlemen, as much for ostentation as use, kept running-footmen—a class of servants active in limb, who ran before them on a journey, or went upon errands of special import. The pedestrian powers of these footmen were often surprising. For instance, in the Duke of Lauderdale's house at Thirlstane, near Lauder, on the table-cloth being one morning laid for a large dinner-party, it was discovered that there was a deficiency of silver spoons. Instantly the footman was sent off to the duke's other seat of Lethington, near Haddington, fully seventeen miles off, and across hills and moors, for a supply of the necessary article. He returned with a bundle of spoons in time for dinner. Again—at Hume Castle, in Berwickshire, the Earl of Home had one night given his footman a commission to proceed to Edinburgh (thirty-five miles off), in order to deliver a message of high political consequence. Next morning early, when his lordship entered the hall, he saw the man sleeping on a bench, and conceiving that he had neglected his duty, was about to commit some rash act, when the poor fellow awoke, and informed Lord Home that his commission had been executed, and that, having returned before his lordship was stirring, he had only taken leave to rest himself a little. The earl, equally astonished and gratified by the activity of his faithful vassal, rewarded him with a little piece of ground, which to this day bears the name of the *Post Rig*—a term equivalent to the postman's field, and an unquestionable proof, as all the villagers at Hume devoutly believe, of the truth of the anecdote. The custom of keeping a running-footman did not cease, amongst noble families in Scotland, till towards the middle of the last century.

When the matter of communication was of particular importance, or required to be despatched to a considerable distance, horsemen were employed; and these, by means of relays of fresh animals, and great toil of body,

would proceed journeys of some hundreds of miles to accomplish what would now be much better done by a post letter. Some journeys performed on horseback in former days would be considered wonderful even in modern times, with good roads. Queen Elizabeth died at one o'clock of the morning of Thursday the 24th of March 1603. Between nine and ten, Sir Robert Carey left London—after having been up all night—for the purpose of conveying the intelligence to her successor James at Edinburgh. That night he rode to Doncaster, 155 miles. Next night he reached Witherington, near Morpeth. Early on Saturday morning he proceeded by Norham across the Border; and that evening, at no late hour, kneeled beside the king's bed at Holyrood, and saluted him as king of England, France, and Ireland. He had thus travelled 400 miles in three days, resting during the two intermediate nights. But it must not be supposed that speed like this was attained on all occasions. At the commencement of the religious troubles in the reign of Charles I., when matters of the utmost importance were debated between the king and his northern subjects, it uniformly appears that a communication from Edinburgh to London, however pressing might be the occasion, was not answered in less than a fortnight. The crowds of nobles, clergymen, gentlemen, and burghers, who at that time assembled in Edinburgh to concert measures for opposing the designs of the court, always dispersed back to their homes after despatching a message to King Charles, and assembled again a fortnight thereafter, in order to receive the reply and take such measures as it might call for. And even till the last century was pretty far advanced, the ordinary riding post between London and Edinburgh regularly took a week to the journey.

In consequence of the inattention of our ancestors to roads, and the wretched state in which these were usually kept, it was long before coaching of any kind came much into fashion. Though wheeled vehicles of various kinds were in use among the ancients, the close carriage or coach is of modern invention. The word *coach* is Hungarian, and the vehicle itself is supposed to have originated in Hungary. Germany certainly appears to have taken the precedence of the nations of Western Europe in using coaches. They were introduced thence into England some time in the sixteenth century, but were, after all, so little in vogue throughout the whole reign of Elizabeth, that there is no trace of her having ever used one. Lord Grey de Wilton, who died in 1593, introduced a coach into Ireland, the first ever used in that country. One was introduced into Scotland—we rather think from France—about the year 1571. It belonged to the famous Secretary Maitland of Lethington, who, during the horrid civil war between the adherents of Mary and those of her son James, made a journey in that vehicle from Edinburgh Castle, which he was holding out for the queen, to Niddry in West Lothian, for the purpose of consulting with some others of her friends—the first time, it is believed, that a close carriage was ever used in Scotland. Fynes Morison, who wrote in the year 1617, speaks of coaches as recently introduced, and still rare in Scotland. For a long time these conveniences were only used by old people, who could not well bear riding. The young and active despised them, as tending to effeminacy, and as not being so quick of movement as the horse. The Duke of Buckingham, in 1619, first used a coach with six horses—a piece of pomp which the Duke of Northumberland thought proper to ridicule by setting up one with eight. Charles I. was the first British sovereign who had a state-carriage. Although Henri IV. was killed in a coach—the only one, by the way, he possessed—his ordinary way of appearing in the streets of Paris was on horseback, with a large cloak strapped on behind, to be used in case of rain. In Scotland, previous to the civil war, coaches were only used by persons of high estate.

In a pamphlet called *The Grand Concern of England Explained*, published in 1673, the writer very gravely attempts to make out that the introduction of coaches was ruining the trade of England. The following is an example of his mode of reasoning:—'Before the coaches were set up, travellers rode on horseback, and men had boots, spurs, saddles, bridles, saddle-cloths, and good riding-suits, coats and cloaks, stockings and hats, whereby the wool and leather of the kingdom were consumed. Besides, most gentlemen, when they travelled on horseback, used to ride with swords, belts, pistols, holsters, portmanteaus, and hat-cases, which in these coaches they have little or no occasion for. For when they rode on horseback, they rode in one suit, and carried another to wear when they came to their journey's end, or lay by the way; but in coaches, they ride in a silk suit, with an Indian gown, with a sash, silk stockings, and the beaver hats men ride in, and carry no other with them. This is because they escape the wet and dirt which on horseback they cannot avoid; whereas in two or three journeys on horseback, these clothes and hats were wont to be spoiled; which done, they were forced to have new very often, and that increased the consumption of manufacture. If they were women that travelled, they used to have safeguards and hoods, side-saddles and pillions, with strappings, saddle or pillion cloths, which, for the most part, were laced and embroidered; to the making of which there went many several trades, now ruined.' But the writer has other reasons to urge against coach-travelling. 'Those who travel in this manner,' he observes, 'become weary and listless when they ride a few miles, unwilling to get on horseback, and unable to endure frost, snow, or rain, or to lodge in the fields.' Besides, he asks, 'what advantage can it be to a man's health to be called out of bed into these coaches an hour or two before day in the morning?—to be hurried in them from place to place till one, two, or three hours within night; insomuch that, after sitting all day, in the summer time, stifled with heat and choked with dust—or in the winter time, starving or freezing with cold, or choked with filthy fogs, they are often brought into their inns by torch-light, when it is too late to sit up to get supper, and next morning they are forced into the coach so early, that they can get no breakfast? What addition is it to men's health or business to ride all day with strangers, oftentimes sick, ancient, diseased persons, or young children crying; all whose humours he is obliged to put up with, and is often poisoned with their nasty scents, and crippled with boxes and bundles? Is it for a man's health *to be laid fast in the foul ways, and forced to wade up to the knees in mire; afterwards* sit in the cold till teams of horses can be sent to pull the coach out? Is it for their health to travel in rotten coaches, and to have their tackle, or perch, or axle-tree broken; and then to wait three or four hours (sometimes half the day), and afterwards to travel the whole of the night to make good their stage?'

These, however, do not exhaust the patriotic clamours of the writer against the odious innovation of stage-coaching. He says that the practice 'discourages the breed of horses,' an argument which, it is amusing to observe, has also been used in opposition to the introduction of railways in recent times. In certain very peculiar circumstances, he allows, stage-coaching might be tolerated, but in no other. 'If some few stage-coaches were continued—to wit, one to every shire-town in England, to go once a week backward and forward, and to go through with the same horses they set forth with, and not travel above thirty miles a day in the summer, and twenty-five in the winter, and to shift inns every journey, that so trade might be diffused—these would be sufficient to carry the sick and the lame, that they pretend cannot travel on horseback; and being thus regulated, they would do little or no harm; especially if all be suppressed within fifty miles of

London, where they are noway necessary, and yet so highly destructive.'

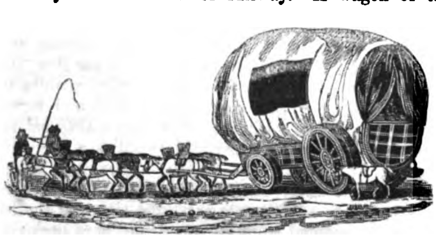
We have thought fit to introduce these extracts here, not so much for the purpose of amusing the reader with their absurdity, as to afford a caution to the general opponents of improvement. Arguments of a similar illogical nature are now used in reference to almost every proposed melioration in our social condition, and will doubtless, in a century hence, be quoted for their short-sighted folly, though at present meeting with countenance from a large class of the community.

Notwithstanding the introduction of stage-coaches in the seventeenth century, they were placed only on the principal roads, and used almost exclusively by persons of refined taste and wealth. The popular mode of conveyance continued for at least a century afterwards to be by stage-wagons; these were very large and cumbersome machines, drawn by six or eight horses, and devoted chiefly to the carriage of goods to and from the metropolis. The only part of the vehicle which afforded accommodation to passengers was the tail of the wagon, as it was called, a reserved space with a hooped-up cover at the hinder part of the machine; and here, sitting upon straw as they best could, some half-dozen passengers were slowly conveyed—we should rather say jolted—on their journey.

The wagons thus employed in the double office of carrying both goods and passengers were, as we have said, confined chiefly to the great lines of road in England. On all the less-important routes, and particularly in Scotland, the only means of conveyance for goods was by packhorses. These animals were loaded with sacks

thrown across the back; and if not too heavy, piled to a considerable height. A number together were generally conducted in a line along the narrow and badly constructed paths, that which went before carrying a bell, by the tinkling sound of which the cavalcade was kept from straggling after nightfall. This primitive mode of conveyance continued in operation in some parts of the country till the year 1780 or thereabouts, when one-horse carts came into use.

The old-fashioned wagons still remain in use in England, notwithstanding the numerous improvements in modes of conveyance and locomotion. They are chiefly employed for the carriage of goods between the metropolis and country towns which are at a distance from any line of canal or railway. A wagon of this



kind is provided with four broad and huge wheels, and is drawn by six large horses, the driver sometimes riding on a separate small pony. The wagons employed in London to convey coal from the wharfs to the houses of consumers, or beer from brewers, are of the same unwieldy form, and are drawn with a needless expenditure of power. Railway traffic, however, is now rapidly diminishing the number of these ponderous vehicles; and the desire for increased speed is as rapidly substituting, on all the common roads, light and elegant spring-vans.

The length of time consumed in journeys by even the best kind of carriages of past times, is now matter for surprise. The stage-coach which went between London and Oxford in the reign of Charles II., required two days, though the space is only fifty-eight miles. That to Exeter (168½ miles) required four days. In 1703, when Prince George of Denmark went from Windsor to Petworth to meet Charles III. of Spain, the distance being about forty miles, he required fourteen hours for the journey, the last nine miles taking six. The person who records this fact says, that the long time was the more surprising, as, *except when overturned*, or when stuck fast in the mire, his royal highness made no stop during the journey.

In 1742, stage-coaches must have been more numerous in England than in Charles II.'s time; but it does not appear that they moved any faster. The journey from London to Birmingham (116 miles) then occupied nearly three days, as appears from the following advertisement:—'The Lichfield and Birmingham stage-coach set out this morning (Monday, April 12, 1742) from the Rose Inn, Holborn Bridge, London, and will be at the Angel, and the Hen and Chickens, in the High Town, Birmingham, on Wednesday next, to dinner; and goes the same afternoon to Lichfield. It returns to Birmingham on Thursday morning to breakfast, and gets to London on Saturday night; and so will continue every week regularly, with a good coach and able horses.' Thus the whole week was occupied in a journey to and from Lichfield by Birmingham, an entire space of probably not more than 240 miles—that is, at an average of forty miles a day.

Of the stage-coach journey to Bath about 1748, we learn some particulars from Smollett's celebrated novel. Mr Random enters the coach before daylight. It proceeds. A highwayman attacks it before breakfast, and is repulsed by the gallantry of the hero. Strap meanwhile accompanies the coach on horseback. A night is spent on the road, and the journey is finished next day, apparently towards evening—108 miles! At that time there was no regular stage-coach from London to Edinburgh; and the newspapers of the latter city occasionally present advertisements, stating that an individual about to proceed to the metropolis by a post-chaise would be glad to hear of a fellow-adventurer, or more, to lessen the expenses for mutual convenience. However, before 1754, there was a stage-coach between the two British capitals. In the *Edinburgh Courant* for that year, it is advertised that—'The Edinburgh stage-coach, for the better accommodation of passengers, will be altered to a new genteel two-end glass coach machine, hung on steel springs, exceeding light and easy, to go in ten days in summer and twelve in winter; to set out the first Tuesday in March, and continue it, from Hosea Eastgate's, the Coach and Horses in Dean Street, Soho, London, and from John Somerville's in the Canongate, Edinburgh, every other Tuesday, and meet at Burrowbridge on Saturday night, and set out from thence on Monday morning, and get to London and Edinburgh on Friday. In winter, to set out from London and Edinburgh every other [alternate] Monday morning, and to go to Burrowbridge on Saturday night; and to set out from thence on Monday morning, and get to London and Edinburgh on Saturday night. Passengers to pay as usual. Performed, if God permits, by your dutiful servant, HOSEA EASTGATE.' Here the distance of 200 miles requires six days in winter, being

at the rate of little more than thirty-three miles a day. So lately as the end of the last century, the journey by the stage between Edinburgh and Glasgow (forty-two miles) occupied a whole day, the passengers stopping to dine on the road. It was considered a great improvement when, in 1799, a coach was started with four horses, which performed the journey in six hours. It is not unworthy of being noticed, that when the mail-coaches were started by Mr Parker in 1788, six and a half miles an hour was the utmost speed attained.

ROADS.

It will appear, from the preceding notices respecting travelling and modes of carriage for goods, that little or no improvement could be expected in either case till a great change for the better was made on the state of the roads. In no branch of art do our ancestors seem to have been more deficient or heedless than in that of making roads, and keeping them in constant repair. In this respect, indeed, they were in a condition of greater ignorance than the ancient Romans, whose roads were on the most extensive and efficient scale, suitable to the necessities of the period, and may here be shortly described.

Ancient Roman Roads.

It is, we believe, generally allowed that the Romans gained a certain degree of knowledge on the subject of road-making from Greece and Carthage, and also perhaps from Egypt; but whatever they learned, they greatly improved upon, and therefore they are entitled to be called the first and best road-makers of whom history has preserved any account. One great leading principle actuated the Roman authorities in establishing roads: it was that of maintaining their military conquests. On vanquishing a barbarous country, their first efforts consisted in penetrating it with good roads, which were maintained with jealous care, and were connected, as far as possible, in unbroken and direct lines with the seat of government at Rome: this indeed formed one of their grandest ensigns of subjugation, and affords us a striking proof of their sagacious and active character.

Speaking of the subordinate Roman capitals in Asia Minor, Syria, and Egypt, Gibbon describes as follows the manner in which they were connected by roads: 'All these cities were connected with each other and with the capital by the public highways, which, issuing from the Forum at Rome, traversed Italy, pervaded the provinces, and were terminated only by the frontiers of the empire. If we carefully trace the distance from the wall of Antoninus [in Scotland] to Rome, and from thence to Jerusalem, it will be found that the great chain of communication, from the north-west to the south-east point of the empire, was drawn out to the length of 4080 Roman [or 3740 English] miles. The public roads were accurately divided by mile-stones, and ran in a direct line from one city to another, with very little respect for the obstacles either of nature or private property. Mountains were perforated, and bold arches thrown over the broadest and most rapid streams. The middle part of the road was raised into a terrace which commanded the adjacent country, consisting of several strata of sand, gravel, and cement, and was paved with large stones, or in some places near the capital, with granite. Such was the solid construction of the Roman highways, whose firmness has not entirely yielded to the effect of fifteen centuries. They united the subjects of the most distant provinces by an easy and familiar intercourse; but their primary object had been to facilitate the marches of the legions: nor was any country considered as completely subdued, till it had been rendered in all its parts pervious to the arms and authority of the conqueror. The advantage of receiving the earliest intelligence, and of conveying their orders with celerity, induced the emperors to establish throughout their extensive dominions the regular institution of posts. Houses were everywhere erected, at the distance of only five or six miles; each of them was constantly provided with forty horses; and by the help of these relays, it was easy to travel a hundred miles in a day along the Roman roads. The use of the posts was allowed to those who claimed it by an imperial mandate; but though originally intended for the public service, it was sometimes indulged to the business or conveniency of private citizens.'

From other accounts, we learn that the Roman roads varied in importance and uses. The great lines were called *prætorian ways*, as being under the direction of the prætors; and these formed the roads for military intercourse. Other lines were exclusively adapted for commerce or civil intercourse, and were under the direction of consuls. Both kinds were formed in a similar manner. The plan on which they were made was more calculated for durability than ease to the traveller; and for our modern wheel-carriages they would be found particularly objectionable. Whatever was their entire breadth, the centre constituted the beaten track, and was made of large ill-dressed stones, laid side by side, to form a compact mass of from twelve to twenty feet broad; and therefore in their external aspect they resembled the coarse stone causeways which are still in use in the towns and highways of France. Some of the roads had double lines of this solid pavement of this nature, with a smooth brick-path for foot-passengers; and at intervals along the sides, there were elevated stones on which travellers could rest, or from which cavalry could easily mount their horses. One important feature in the construction of all the Roman roads was the bottoming of them with solid materials. Their first operation seems to have been the removal of all loose earth or soft matter which might work upwards to the surface, and then they laid courses of small stones, or broken tiles and earthenware, with a course of cement above, and upon that were placed the heavy stones for the causeway. Thus a most substantial and durable pavement was formed, the expense being defrayed from the public treasury. Various remains of Roman roads of this kind still exist in France, and also in different parts of Britain. One of the chief Roman thoroughfares, in an oblique direction across the country from London to the west of Scotland, was long known by the name of Watling Street, which has been perpetuated in the appellation of one of the streets in the metropolis.

Modern Roads.

For a description of these, and the most improved methods of construction, we beg to refer the reader to the number on CIVIL ENGINEERING. With respect to the maintenance of roads, the most advantageous plan consists in assigning the entire duty to a contractor. The trustees appointed by local acts of parliament to superintend highways, now generally employ contractors to keep the roads in repair at a specified price per mile. The cost of maintenance, interest on capital, &c., are defrayed from a tax levied at the toll-bars or turnpikes.* To say nothing of the annoyance of the system, this mode of raising the necessary funds is the most wasteful that could be contrived; on an average, 44 per cent. is absorbed in collection alone. Some years ago, Mr Pagan, a Scottish country solicitor, proposed a plan for the entire abolition of toll-bars, the consolidation of trusts, and the levying of an annual rate on horses. He demonstrated, taking the county of Fife as an example, that on his plan the roads could be maintained at little more

* Turnpikes were so called, from poles or bars, swung on a pivot, having been placed on them, and turned either way when dues were paid. Gates are now substituted for these poles in Great Britain. In Germany, the pole is still used, one end being depressed to raise the other, and so permit a free passage.

than one-half their present cost. Notwithstanding the utter indefensibleness of the existing system, it has as yet been impossible to bring the local trusts to take any steps towards realising the plan; but the subject is beginning to be again agitated, and there is some hope that a national measure may be adopted for the abatement of this nuisance.

Law of the Road.—For general convenience and safety, drivers of vehicles and riders, in travelling along a road, are expected to take a particular side; and this practice is now so well understood, and is in itself so proper, as to have become a part of the common law. The law of the road is, that when drivers meet from different directions, each shall keep his left hand to the wall or footpath. Secondly, when one driver overtakes another, and wishes to pass him, he must keep his left hand to the vehicle which he passes. In the case of either meeting or passing, each party is entitled to the half of the road. The same rules apply to riders. If these regulations be neglected, and an accident occur, the law is always in favour of the party who kept his own proper side, and no excuse can shelter the aggressor. The trustees of the road are liable in an action of damages for any injury that may be sustained through the carelessness of themselves or servants in leaving the road grossly out of repair.

According to a well-known rule, foot-passengers on pavements or side-paths are expected to walk with their right hand to the wall—that is, they keep their left hand to those whom they are meeting and passing. This custom prevents confusion in the streets of large towns, but is not a matter of law.

CANALS.

A canal is an artificial channel of water, and is usually constructed for inland navigation. Where rivers can be resorted to for purposes of this kind, they are preferable to canals, because little expense may be required to suit them for navigation, and they may be easily kept in repair. But few rivers, generally speaking, are sufficiently level, straight, or deep, to admit of being profitably navigated by barges, and therefore artificial channels require to be cut. Canals are extremely suitable in level countries possessing rivers or brooks which can afford a due supply of water. In China, from a very early age, certain large rivers have formed natural canals longitudinally through the country from west to east, while artificial canals have been made to proceed in a cross direction from north to south, thus effecting a universal water-communication throughout the empire. Canals existed in ancient Egypt in connection with the Nile, on a similar plan to what now prevails in China. Notwithstanding that canals were known to have existed from a remote antiquity in the East, it was long before they were introduced into Western Europe. In modern times, they were first used by the inhabitants of the Netherlands, in consequence of the extreme flatness of their country, and the numerous channels of water which intersect it in all directions, in connection with the lower branches of the Rhine and other rivers. In Holland and Belgium, therefore, canals in a great measure exist as an essential requisite in the general arrangements of the country, and are, in point of fact, so many ditches or drains to receive the superfluous waters.

In countries differently constituted, canals are constructed only with reference to the profit in the form of commercial speculation. The great question, accordingly, in forming the project of a canal, is, whether the anticipated amount of traffic will raise tolls sufficient to compensate the outlay of the undertaking and subsequent charges for repair and superintendence. It simplifies such an inquiry to know the following truths in reference to cost of conveyance:—The cheapest mode of conveyance is by coasting-vessels, steam-boats, &c., and these will at all times be employed for heavy and bulky goods—such as coal, barrels of liquids, iron, and other cumbrous materials proceeding coastwise. The next cheapest mode of conveyance is by barges on rivers; and the next is by means of canals. After this are ranked, in point of economy, conveyance by land on railways and roads, the last being the dearest, though often the only means of transport which can be obtained. According to this view, canals can never answer as profitable speculations when they have to compete with coasting-vessels of any description, or with any species of conveyance by rivers. They cannot even, in certain circumstances, compete successfully with railways, on account of the slowness of speed at which barges or boats are drawn along them; and as speed is becoming daily a matter of greater moment in traffic, canals are gradually losing the conveyance of every kind of goods for which quickness of transit is desirable. For the sake of economy in national resources, it is very desirable that these truths in statistics should be generally understood and remembered.

While, however, the trade on some of the lines of canal, since the introduction of railways, has sunk in an extraordinary degree, it is a remarkable fact, and one in every way worthy of notice, that in some districts where a large amount of traffic has been developed by railways, that canals in their immediate neighbourhood have suffered no loss from the powerful opposition, but, on the contrary, their trade has been increased. Thus, 'notwithstanding the enormous traffic conveyed along the London and North-Western rails, the quantity carried along the Grand Junction Canal, which meanders alongside its powerful antagonist, instead of having been drained, as might have been expected, to zero, has, from the opening of the railway in 1836 up to the present period, actually increased, as follows:—Average amount of goods annually moved on the Grand Junction Canal during the three years prior to the opening of the London and Birmingham Railway in 1836, 756,894 tons; average amount of goods annually moved during the *twelve* years subsequent to 1836, 1,039,333 tons.'

In order to meet the requirements of modern commercial traffic, in which *speed* is an essential feature, attempts have been recently made to adapt steam-power to canal traction, but with very limited success. It may not be generally known that the principal obstacle to the use of steam-engines on board canal-boats, is the injury done to the banks by the action of the water from the paddles. This obstacle has to a certain degree been overcome by the use of one-paddled boats—the paddle being placed in the line of the boat's keel; and also by the application of the Archimedean screw-propeller. Still, steam-dragging is by no means general; and canals, as a superseded idea, do not now much occupy the attention of engineers and inventors. It has also been proposed to lay rails along the towing-path, and employ steam-drags—a notion somewhat superfluous in these days, when it would be quite as economical to convert the path into a railway at once, or even to lay dry the canal, and apply its course to a similar purpose.

One of the largest canals in Europe is that which extends from the German Ocean to the river Y, at Amsterdam, by which vessels are enabled to reach that city by a direct channel, instead of sailing round by the Zuiderzee. This ship-canal was begun in 1819, and finished in 1825, at an expense of £850,000. Its length is nearly 52 English miles; its breadth 125 feet at the surface, and 38 feet at the bottom; and its depth 20 feet 9 inches. Traversing a perfectly flat country, it has no locks, except at its extremities, and is of such magnitude, that two frigates, or the largest merchant-vessels, can pass each other. There is a towing-path for horses on each side; and about eighteen hours are required to perform the voyage from Amsterdam to the ocean. As a commercial speculation, the canal yields no profit, but its service to the shipping of Amsterdam

is incalculable, and without it the town must have sunk into comparative insignificance.

France possesses about fifty different canals, some of which are of great importance for general traffic. The chief canal is allowed to be that of Briare, called also that of the Loire and Seine. It was completed in 1642, measures 34½ miles in length, and has 40 or 42 locks. The width is 25 feet at bottom. By this canal, Paris receives large supplies of inland produce. The Canal du Midi, or Languedoc Canal, makes a communication between the Mediterranean at the city of Cette and the Atlantic Ocean at the mouth of the Garonne, passing through the province of Languedoc. Altogether, there are nearly 1000 miles of canals in France.

The United States of North America possess upwards of 2500 miles of canals, the whole of which have been constructed within the last forty years. The principal undertaking of this kind is the Erie Canal, which unites the river Hudson at Albany with Lake Erie at Buffalo, a distance of 363 miles. The Miami Canal, from Cincinnati to Lake Erie, which extends 265 miles, is another great undertaking; and there are a number of other canals, scarcely less important, for the general traffic of the country. The canals of Canada are also on a great scale. The Rideau Canal, 135 miles long, connects the town of Ottawa—formerly Bytown—on the river Ottawa, with Kingston on Lake Ontario. By means of the Welland Canal, 28 miles long, connecting Lakes Erie and Ontario, and of the St Lawrence Canal, 41 miles in length, for avoiding the rapids of that river, communication is now open, for sea-going vessels, from the Atlantic to the most western ports on the Canadian lakes. In 1856, a cargo of wheat was brought from Chicago to Liverpool without transhipment.

The canals of Great Britain are believed to extend to an aggregate length of 2400 miles. The greater part are in the midland districts of England, including Lancashire, and have for their object the connection of the large seats of manufacture with the sea on both sides of the island, and with the Thames at London. The Grand Trunk Canal, connecting the Mersey with the Trent and Humber, extends 93 miles. The Birmingham and Worcester connects the Grand Trunk Canal with the Severn. The Grand Junction connects the Grand Trunk with the Thames. Thus the four great ports of the kingdom—London, Bristol, Liverpool, and Hull—are connected by canals. So generally are these and other canals spread over England, that it is supposed there is not a place south of Durham more than fifteen miles from water-communication.

Ireland has about 300 miles of canals, mostly government undertakings, and in general possessed of little trade. Scotland has a number of canals, but they are chiefly confined to the western and mid district of the country. That which possesses the largest traffic is the Forth and Clyde Canal, reaching from the Clyde, a short way above Dumbarton, to the Forth at Grangemouth. This canal, which was opened in 1790, and affords a ready communication for small vessels between the east and west coast, extends 39 miles in length; its highest level is 160 feet, with 20 locks on the eastern acclivity, and 19 on the western. The canal is connected with Glasgow by a side-cut; and it is joined by the Union Canal, which extends from near its eastern extremity to Edinburgh. The Caledonian Canal is formed in a great measure by a chain of lakes, stretching across the country from Inverness on the east to Loch Eil on the west coast, a distance of 59½ miles. The canal part is 20 feet deep, 50 feet wide at bottom, and 120 feet at top, which affords a passage to frigates of 32 guns, or merchant-vessels of a similar size. This great canal was undertaken as a public work by government; and after a labour of eighteen years, was opened in 1822. It possesses 13 locks on the east, and 12 locks on the west declivity, the highest level being 94 feet. By this canal, the dangers of rounding the northern extremity of the island by the Pentland Firth may be avoided; but, from the prejudices of seamen, it has never been much used. As a means of allowing steam-boats to run between the Clyde and Inverness, the canal has been of considerable public service. The expenditure for construction, repairs, and maintenance, up to 1855, was £1,361,704; of which £1,242,367 had been derived from public grants, and only £85,614 from canal dues.

Two great undertakings, which invite the concurrence of all commercial nations, have been projected and discussed for years: a canal, namely, across the Isthmus of Panama, to unite the Atlantic with the Pacific; and another from the Red Sea to the Mediterranean, over the Isthmus of Suez. Neither undertaking has yet got further than surveys and estimates.

RAILWAYS.

Before the practice of steam-navigation had attained that degree of improvement which it now possesses, a not less wonderful mode of travelling by steam-power on land had come into use; so that during the first thirty years of the nineteenth century, infinitely greater improvements in the means of locomotion have been discovered and brought into practical operation for the benefit of mankind, than had ever previously been known. To understand and value the application of steam-power to land-travelling, we must advert to the subject of draught on common roads.

There exist three obstacles to the rapid motion of carriages—terrestrial attraction, the atmosphere, and friction. By no human power can the first two be removed, but the latter can be so far modified as to form little or no opposition. On common roads, the friction is generally so great as to absorb a large percentage of the force expended in drawing the carriage. To reduce this, tramways or continuous parallel lines of smooth stone are sometimes laid down on steep roads; but the use made of them by careless drivers does not compensate for the expense of their construction.

The draught of a horse upon a macadamised road may be set down at a ton, and the highest rate of speed at which horses can go, when dragging a weight, at ten miles an hour. These data shew how far horse-power is from being fully available for the great purposes of commerce. Two hundred horses were necessary to perform the journey of the mail from Edinburgh to London, a distance of 400 miles—the time expended being forty-three hours, and relays of four horses being required at every eight miles. This rate of locomotion being attained, by improvements on roads, carriages, and in the breed of horses, nothing more could be done. Something new required to be devised.

The idea of employing steam-power to drag carriages over common roads, and thus save a large outlay for horses, besides accomplishing a greater speed, was suggested by various enterprising minds, but to its practical application there were, and are, many serious objections. Independently of the ordinary and unavoidable roughness of common roads, all highways are less or more uneven; because to construct them upon a perfect level throughout, would be attended with an expense which the tolls from any traffic could not sustain. The general unevenness of roads, therefore, causes a great loss of drawing-power. In these circumstances, it is evident that, for the avoidance of friction and economising of forces, an entirely new species of road required to be contrived. This important desideratum is found in the invention of *railways*. The design of a railway is to furnish a hard, smooth, and unchanging surface for wheels to roll upon. No provision, as respects smoothness, is required for any part of the path, except the narrow lines which are immediately to come under the rim of the wheels.

The earliest railway of which there is any account was one constructed near Newcastle-upon-Tyne. In Roger North's *Life of Lord Keeper North*, he says that at this

place, in 1676, the coals were conveyed from the mines to the banks of the river 'by laying rails of timber exactly straight and parallel; and bulky carts were made, with four rollers fitting those rails, whereby the carriage was made so easy, that one horse could draw four or five chaldrons of coal.' One hundred years afterwards, about 1776, Mr Curr constructed an iron railway at the Sheffield colliery. The rails were supported by wooden sleepers, to which they were nailed. In 1797, Mr Barns adopted stone supports in a railway leading from the Lawson main colliery to the Tyne, near Newcastle; and in 1800, Mr Outram made use of them in a railway at Little Eaton, in Derbyshire. Twenty-five years afterwards, this species of road was successfully adopted on a public thoroughfare for the transportation of merchandise and passengers—namely, the Stockton and Darlington Railway, which was completed in 1825, and was the first on which this experiment was made with success. From that time, accordingly, a new and wondrous era commenced in the history of inland conveyance.

It is a remarkable circumstance, that the early practisers of railway transport could not imagine that a carriage, moved by steam-power, could proceed along the rails without the aid of toothed wheels and a rack; and to overcome this imaginary difficulty, no small degree of expense and labour was fruitlessly incurred. About the year 1815, Mr Blackett of Wylam, near Newcastle, effectually proved, by repeated experiments, that the adhesive power of the wheels on the rails was at all times sufficient to cause a progressive motion in an engine, with a train of loaded carriages, upon a railway either level or with a small acclivity. Important as was this discovery, fifteen years elapsed before steam-locomotives were fairly established. This great triumph of art occurred in connection with the opening of the Liverpool and Manchester Railway on the 15th of September 1830, since which period railways have spread to all populous parts of the country.

Simple as is the idea of a railway, a prodigious expense is necessarily incurred in bringing it into practical operation. In addition to the cost of construction, the purchase of the land over which the railway runs, and the preliminary expenses of obtaining a parliamentary act, amount often to vast sums. The parliamentary expenses alone are not seldom as much as £2000 per mile. The cost of railway construction, however, with all the recent improvements, is now much less than formerly, and may be set down as from £16,000 to £30,000 a mile. The Belgian railways cost £12,600 per mile, on an average. In America, where the lines are mostly single, the average cost has been £6866, and would have been much less but for the protective duties imposed on foreign rails. In Scotland, single lines have been lately constructed at little more than £4000 per mile.

For explanation of the various points connected with the construction of railways, we refer the reader to the number on CIVIL ENGINEERING; and proceed at once to give some notices respecting their management and their commercial features.

At the period of the opening of the Liverpool and Manchester Railway—the first on which steam-locomotion was tried on a large scale—no one, even of their most sanguine supporters, seemed to entertain the slightest notion of the immense importance which railways would assume among the commercial interests of the nation, and as aiding our great industrial operations. The amount of money already sunk in the construction of railways in the United Kingdom seems almost fabulous. Only twenty-six years have elapsed since the system was successfully inaugurated; but in that brief space—how brief in the history of a nation!—8000 miles of railway have been opened, and in their construction have been spent upwards of £300,000,000 sterling! If we further take into account the mileage opened in our various colonies, we may form some idea of the commercial importance of the railway system of the empire. But not only from this point of view must the subject be considered—we must remember the large amount of money circulated by the employment of so many people engaged in the working and maintenance of the lines, and the manufacture of the various materials and machines connected therewith. While, however, it is gratifying to see this evidence of the wealth of our country, which in so short a time could bear so large a drain upon its resources without materially interfering with the usual operations of commerce, it is but right to state that their commercial success, as paying or lucrative concerns, has not been commensurate with the expectations of their projectors. Thus Mr Chattaway (*Railways, their Capital and Dividends*. Weale, London) estimates that there are 'in the United Kingdom twenty-eight railways which yield no return upon their ordinary share-capital; in other words, upwards of £22,000,000 of the capital invested in these important undertakings is utterly unproductive.' And of the paying lines, the experience of the last five years—'five years,' as the same authority remarks, 'of almost unexampled commercial prosperity'—shewed an average of three shillings per cent. of a dividend per annum.

To enter fully into the causes of this would take up more space than we can allow, although the subject is one of importance, as furnishing useful lessons for enabling parties to judge of the probable success of future undertakings. We must therefore content ourselves with a very brief glance at the chief points involved. Of the capital expended in connection with the railway system during the last twenty-six years, there is a large amount, none of which was actually spent in furtherance of the main object—the *construction* of the railway, from the traffic of which the dividends were to be obtained. Many of the schemes were brought forward at a time when a mania for speculation infected nearly all classes. Under this influence, sums of money, seemingly inexhaustible, were thrown without restriction into the hands of the promoters of the schemes; and these sums they recklessly squandered in a multitude of ways, few of which had a direct bearing on the purpose intended, and which were summed up in the convenient phrase, 'preliminary expenses.' And in the instances where construction was set about, the same lavish expenditure characterised all the proceedings; engineers, surveyors, draughtsmen, and engravers were engaged at most extravagant rates. In this way immense sums were needlessly thrown away. And to this must be added the unnecessary and lavish expenditure on the works themselves. Need we instance the money sunk in buildings of elaborate architecture and immense extent, and these often at insignificant stations; double lines laid down where single ones would have sufficed; expensive materials and structures adopted where the simplest would have served the purpose; and all the details of construction carried out with the same minuteness and finish, as if the engineer had been experimenting to discover the most expensive mode of operation, or as if he had been making a model for a museum! It is well known that many expensive and elaborate engineering works might have been avoided; and it is even said that some engineers were more solicitous to carry out operations in which their skill would be displayed, than anxious to secure the commercial success of the line.

Another fruitful source of loss was the practice of what is called *guaranteeing*. The formation of a multitude of branch-lines, connecting the neighbouring towns and villages with the main-line, was encouraged by the directors of the latter guaranteeing a certain rate of dividend on the capital of the branch. This was done with a view to prevent the traffic of these places being diverted into rival lines, in *esse* or *posse*, and to have the branches as feeders to the main-line. These advantages were in nearly every case illusory; scarcely a branch-

line has been found to pay its own working expenses; and many of the lines to which 8, 9, and even 10 per cent. was guaranteed, brought in *nil*, while some paid only 1 and 2 per cent. 'Of all the causes which,' says Mr Chattaway, 'have tended to depreciate the value of railway property, none have had a more prejudicial effect than the system which has obtained of recklessly guaranteeing other undertakings, and of constructing branches through districts possessing no remunerative traffic. Trunk-lines containing within themselves all the elements of prosperity, have thus been brought to the verge of bankruptcy.'

But while railway companies have of themselves been guilty of great extravagance, they have been also the victims of two systems, which have forced them into large expenditure: we refer to the parliamentary expenses, and the system adopted by landowners and holders of property, of asking monstrous sums for plots of land or houses through which the railway was designed to pass, and of throwing every obstacle in the way of the promoters, and driving them into expensive litigation. It is impossible to estimate the loss sustained from these two causes alone: for parliamentary expenses, it is calculated that no less a sum than £14,000,000 has been required. The parliamentary expenses of some railways are almost incredible; the Blackwall Railway, for instance, spent in this way nearly £15,000 a mile. Half a million has been spent in obtaining a railway act; while on another railway the solicitor's bill amounted to nearly a quarter of a million. On an average, it may be computed that the parliamentary expenses of existing railways have exceeded £1000 per mile. The mere statement is enough to excite indignation, when we consider that every railway is calculated to promote the welfare of the district through which it passes, and in consequence, should meet with the fostering care of the legislature, rather than with the hinderances and outlay which its way of proceeding involves. In the opinion of good authorities, the whole of our railway laws could be put upon a very simple and efficient basis at little expenditure. It is to be regretted that all our enactments have been characterised by a vacillating, uncertain policy; so much so, that this cause alone has been reckoned 'as one of the principal causes' of the depressed condition of railway property. As to the other cause of unnecessary expenditure forced upon railway companies, the numerous instances of rapacity and unscrupulous dealing on the part of holders of land, &c., redound little to their credit. In almost every case the company has been considered a fair object of plunder; and to get the most out of it, without regard to the principles of honesty and fair-dealing, seemed to be the object of nearly every proprietor who had property to dispose of. Thus, land worth £5000, has been sold to a company for £120,000; £50,000 has been asked in the first instance, and less than £1000 accepted, but this, after litigation. The opposition of landowners to lines passing through their estates has been bought off at an expenditure of £50,000, £60,000, and £120,000; and what renders these instances all the more disgraceful, the opposition has been simulated. The dealings of the British public in this matter, as well as in the still more celebrated line of railway speculation, form a dark chapter in the commercial history of the people. The lessons to be learned from the history of these errors, and worse than errors, are obvious, and it is to be hoped the public will profit by them in the future. As regards the probable paying capabilities of any projected line, Mr Chattaway says that it may be laid down as an axiom, that if it costs £30,000 a mile, or even approximates to this, 'the old standard,' the receipts will not pay for the outlay; but if, on the other hand, the cost is 'limited to £10,000 or £12,000 a mile,' the line will 'indubitably afford a good return to its shareholders, however thinly populated and unpromising may be the district through which it runs.' With reference to the commercial improvement of railways constructed on the old system of lavish expenditure, the same excellent authority has the following suggestive remarks: 'Inventive genius and mechanical skill, which are constantly economising the cost of production of all the staple articles of manufacture in this country, will yet accomplish much for railways. Improvements in the construction of permanent way and rolling stock; expedients for lessening the immense wear and tear, which are the result of carrying heavy loads at high velocities; improved means of generating and applying steam-power; and possibly the substitution, ultimately, of some more economical, but equally powerful agent—all will tend to lessen the heavy working charges which now press so severely upon railway resources. Further than this, we may reasonably expect, that by the aid of accumulated experience, railway working will become virtually a science; that greater immunity from accident will be obtained, consequent upon more perfect arrangement; and that by placing at the head of departments men of known ability and enlarged views—men who possess the art of conducting, in the readiest manner and to the greatest advantage, the vast amount of traffic which railways have developed—these important undertakings will eventually be raised from their present state of depression.'

There is perhaps no point connected with the railway system possessing more interest than that of the amount of traffic *created* by it. Previous to the opening of the Liverpool and Manchester Railway, estimates were made of the probable amount of traffic in passengers and goods: these are in strange contrast to the results of experience. Thus, it was estimated that 250 people would be the average daily number of travellers. The traffic of 1845 shewed a result of six times the number. Railways have not failed as commercial speculations in consequence—as some have asserted—of actual traffic being far below the estimated; on the contrary, the traffic, in nearly every line opened, has progressively improved from year to year; and this result is noticeable even when comparing the traffic of bad or commercially depressed years with that of good ones. Thus, in 1844—a year of great commercial prosperity—the number of passengers travelling on the London and North-western amounted to 1,896,068, and the total receipts from all sources £1,493,226—the number of miles run over being 82,522,861, in passenger-trains only; while in 1848—a year of great commercial and general depression—the number of passengers was 5,999,347, the total receipts, £2,194,092, and the number of miles run over, 195,129,791. In the half-year ending December 1849, the number of passengers conveyed on all the railways of the United Kingdom was 35,073,672; for the half-year ending December 1850, 41,087,919; and for the half-year ending December 1851, 47,509,392. In 1854, the total number conveyed was 111,206,707—of which England and Wales had 92,346,149; Scotland, 11,949,388; and Ireland, 6,911,170: the number of miles travelled over in England being 1,379,249,238; in Scotland, 146,244,120; and in Ireland, 96,555,135. In England, in the same year, the number of passengers in each train averaged 85; and the average distance travelled over by each passenger, 15 miles; the average sum received from each being 25·05d. In Scotland, these averages were—94; 12·2; and 15·20d.: and in Ireland, 81·4; 14; 18·12d. In England, the revenue from passengers amounted to £7,896,502; from goods, £8,567,264; and for mails, horses, and carriages, £879,257. In Scotland, the passengers produced £756,870; the goods, £1,147,656; and the mails, &c., £93,791. In Ireland, £521,637 were realised from passengers, £255,847 from goods, and £96,956 from mails, &c. The gross revenue of the railways of the United Kingdom is nearly twenty millions and a quarter, the average daily number of passengers 304,676, and the daily receipts £55,386.

That the passenger traffic is capable of still further extension, at least among the middle and lower classes, is evident. We believe that the paying capabilities of cheap excursion-trains are little understood by railway companies, and that erelong a great development of this branch will be witnessed, when once they bring their energies to bear upon the question. Ample evidence of the existence of a large mass of the population, who will only travel when induced by the temptation of low fares, is met with in the experience of the railway companies in the manufacturing districts of England. Nor do the advantages resulting from low fares rest here; we believe that a due revision of the traffic department of all railways, with a view to the adoption of a lower tariff of rates, would be beneficial in developing a large amount of *business* traffic. As it is, a large percentage of the steam-power is expended in dragging empty carriages; trains rarely carry more than half their load. By proper management, this will in time be avoided, or greatly obviated. It is impossible to overrate the importance of endeavouring to establish a lower rate of charges than at present obtains. 'Cheapness of fare,' says the Report of the Committee of the House of Commons, 'may create a traffic which otherwise could not possibly exist.' If a traffic of 20,000 tons requires a charge of 10½d. a mile to make it remunerative, a traffic of 1,000,000 tons would be remunerative at about a *halfpenny per mile*.

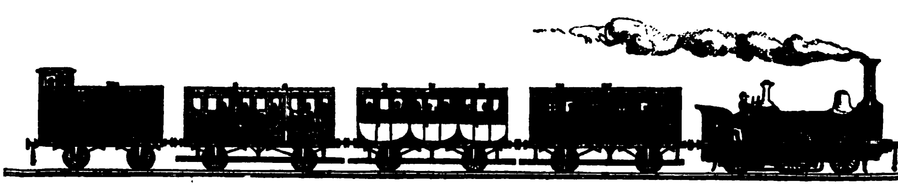
The railway system now extends more or less over all Europe, and is even penetrating into Asia and Africa. It was calculated by Dr Lardner, that in 1850 the gross receipts of the European railways amounted to £23,309,000, of which £12,755,000, or about the half, was collected on the railways of the United Kingdom. The receipts in the United Kingdom are since then nearly doubled; and we may assume that in the rest of Europe the increase of railway locomotion has been still greater. In America, railways are undergoing an extraordinary development. In 1848, the number of miles was 6000, and in 1853, it was 14,508. Massachusetts alone, with a population about one-third that of Scotland, had 1200 miles of railway. The existing railways in 1856 are stated at 20,000 miles; and it is anticipated that before 1860 they will exceed 35,000 miles. Both the construction and management of American railways are on a more simple and economic scale than in Europe.

In considering the immense number of passengers that travel yearly on our railways, another point of interest is opened up to us—namely, the amount or percentage of accidents happening in consequence. Statistics on this point prove very conclusively that railway travelling is much safer than stage-coach travelling. Although an accident by railway is terrible in its results, as compared with that of a stage-coach, we must remember that accidents less frequently happen, and that the number of passengers travelling at the same time is much greater in the former than in the latter. The chances of being killed are one in every half-million nearly; and of being injured, one in 120,000. Thus, for the year ending December 1851, 47,509,302 passengers travelled in the United Kingdom, out of which 113 were killed, and 264 injured—of whom 9 were killed, and 14 injured owing to their want of caution, or their own misconduct. But out of 113 killed, only 17 were passengers, the remainder being servants of the companies or contractors. A novel species of insurance, and one to which the railway system has given rise, is the 'Railway Passengers' Insurance.' The following is given by Mr Williams as the principle upon which the company is established: 'If every traveller, during the second six months of 1851 had paid a penny for every journey, into a relief-fund, the amount realised would have been £197,955. This would have permitted the payment of £1000 to the representatives of each person killed, and of £250 to each person injured. Each railway traveller pays, on an average, about 1s. 8d. each journey; so that an additional penny would have secured for these poor sufferers the most incalculable relief.' The company has made arrangements by which insurance-tickets can be had at nearly every station in the kingdom at the following rates: Threepence to insure £1000 in case of death, for first-class passengers; twopence for £500 for second, and one penny for £200 for third-class passengers, with compensation in case of injury. Only a small percentage of railway passengers avail themselves of this excellent provision; according to the experience of the company in 1851, but one in every 183.

Considering the immense number of passengers that travel by railway, and the almost incredible number of miles run over by them, it is gratifying to witness the small percentage of accidents. It has been the fashion to blame railway companies for their carelessness, and their indifference to the value of life; but a close investigation will prove that really the pains they take to prevent accidents is very great. The various contrivances and plans adopted to insure this, it is now our duty to notice.

Signals.—The signals employed at stations, though apparently complicated, are in reality very simple. Red always denotes 'danger,' and conveys an injunction to the guard to 'stop' the train; green, 'caution,' or to drive slowly; white, or no signal, means 'all right.' Coloured boards, elevated on posts, are generally used for day-signals. The signal is shewn by turning the board across the line of the rails; when no signal is meant to be shewn, the edge of the board is turned towards the driver. Instead of coloured boards, a movable arm is sometimes attached to the mast; raised at right angles, it signifies 'danger;' sloping at 45°, it signifies 'caution.' When dark, a lamp, elevated on the signal-post, is made to shew a white, green, or red light, by means of movable glass slides. The boards and slides are moved by wires, the signal-posts being generally at some distance from the station. Sometimes there are two sets of signal-posts, main and auxiliary. Flags and hand-lamps are also used for particular purposes. In long tunnels, the electric telegraph is used to communicate with the policeman at either end. In thick foggy weather, the various ordinary signals are rendered useless, and fog-signals are put in requisition: these are composed of a detonating mixture placed between disks of metal, the whole being clasped to the rail. The disks lying on the upper side are crushed by the engine-wheels passing over them, and a loud report is heard, which acts as a danger-signal.

Carriages.—The distinction between the different



classes of carriages used, and their fittings, is so well known, that we need not take up space by any description; suffice it to say, that in no department has there been so little progressive improvement shewn

as in that of carriages. The cut represents a train composed of locomotive, first, second, and third class carriages, and a luggage-van, containing the guard's box. The locomotive is usually followed by a separate carriage, called a *tender*, carrying a supply of fuel and a cistern of water; in the form of locomotive here represented, which is adapted for short distances, the supplies are carried in a compartment on the locomotive behind the driver.

To lessen the amount of concussion between the carriages, each is provided at back and front with *buffers* —that is, cushioned steel rods acting upon springs which are made capable of resisting a high degree of pressure. To prevent oscillation during high rates of speed, none of the plans proposed are, we believe, so efficient as well-balanced and well-constructed wheels and carriages. Accidents frequently happen from the insecurity of the *couplings;* to remedy which, various contrivances have been tried. In Mr Chattaway's patent buffing and coupling apparatus, the buffer and draw-hook are combined and placed in the centre of the carriage, instead of having the buffers at the corners, as is usually the case. A portion of the rod is screwed, and fitted with an adjusting apparatus, by which the coupling may be disengaged or tightened up as desired. 'By this method, separate corner-buffers and side-chains are dispensed with, the buffing, drawing, and coupling apparatus being all combined on one central rod.' Central buffing, according to good authorities, is in every way preferable to the present system of having corner-buffers. In connection with the safe working of railways, the *brake* or *break* is of first importance; and on this contrivance a large amount of mechanical ingenuity has been brought to bear. The break consists of a set of wooden blocks, which are made to press against the wheels by means of a system of levers. In general, the break only influences the particular carriage on which it is fixed; but in Mr Newall's, which we are about to describe, and which is now accepted as a reliable and efficient appliance by railway authorities, the guard is enabled to work simultaneously all the breaks in the train. The connection between the breaks throughout the train is made by carrying tubular shafting over or under the carriages; and this is fitted up so as to accommodate itself to the varying movements of the train. Through this shafting, both the engine-driver and the guard are enabled to work all the breaks. At one end of the break-van or carriage, there is a hollow cylinder, four feet in length and four inches in diameter, which is fixed perpendicularly against the carriage. A spiral steel spring works in this cylinder, and actuates a cross-piece, whose movement is communicated directly to the lever of the break. The expansion of the spring forces down the cross-piece and applies the break. To release it, the cross-piece has attached to it a rack, which the guard raises by turning a hand-wheel and pinion. This compresses the spring; and to retain it in this position till the break is again required, a catch is applied to the pinion. In other forms of break, there is no spring; but the end of a vertical screw, which is turned by a hand-wheel, acts directly on the lever-system that applies or withdraws the wooden blocks.

It is of great importance that the guard and the engine-driver should be able at any instant to communicate with each other. The simplest plan yet introduced, for effecting this object, is the following, which has been recommended by the Railway Clearing-house (see page 430)—it is right, however, to state that there is by no means a uniformity of opinion as to its efficiency. A single strike-bell is affixed to the engine-tender, as near as possible to the place usually occupied by the driver. A strong cord actuates this, which is carried along the sides of the carriages to the guard's van, and is there wound round a wheel, to which a balance-weight is attached, to keep the cord tight—allowance of course is made for the variation in the length of the train. The bell is struck by the guard turning the wheel rapidly.

For the security of railway conveyance, a primary point is the keeping of the permanent way in perfect order. The arrangements for this are very complete, and are most rigidly followed out. 'Overlookers' are appointed to each section of the line; under these officials are foremen, whose duty it is to examine with care every morning each portion of the rails, chairs, and sleepers. Should repairs be required, precautions are taken to signal the trains, and workmen are summoned according to the exigency of the case. When the repair is of some extent, as in the relaying of a portion of the rails of the line, instructions are forwarded to the engine-drivers and the workmen employed, so that little interference with the working of the trains and the relaying may result.

When the railway passes on a level with an ordinary road, special means are taken to prevent accidents. A policeman is in constant attendance at the spot, whose duty it is to stop the ordinary road-traffic by closing the gates, at each side of the railway, before the time a train is expected to pass. When the road is opened for traffic, the gates are placed across the line of rails.

Locomotives.—Locomotives are now made of greater power and weight than at first, requiring a corresponding increase in the strength of the rails. Instead of the original locomotive of four or five tons, costing some £500 or £600, we now have them traversing our railways of twenty to forty tons-weight, involving an outlay of £2000 or £3000. The power exerted by some of the first-class engines is enormous: on the broad gauge, express engines have been introduced equal to the dragging-power of 700 or 800 horses, and capable of hurrying trains along at the rate of 60 miles an hour; the consumption of coke being 20 pounds per mile, and the pressure of steam 120 pounds to the inch. Engines of equal or greater power are in use on the narrow-gauge lines—one on Crompton's patent, exerts a power equal to 1140 horses. Originally, locomotives were supported on four wheels; they are now constructed generally with six, and sometimes eight—the diameter of the driving-wheels varying from six to eight feet. For a description of the locomotive, its arrangement and construction, we refer the reader to the article on the STEAM-ENGINE.

The following account of one of the ordinary engines for passenger traffic on the Great Western Railway may be interesting. It is capable of taking a passenger-train, of 120 tons-weight, at an average speed of 60 miles an hour. The power is equal to 1000 horses theoretically, but of 743 when tested by the dynamometer. Its weight, with coke and water, is 35 tons; the empty tender weighs 9 tons, and it usually carries 30 hundredweights of coke and 7 tons of water. There are 305 tubes in the boiler, giving a heating surface of 1759 feet, and the fire-box gives 150 additional. The diameter of cylinder is 18 inches, length of stroke, 2 feet, diameter of driving-wheel, 8 feet. The actual consumption of fuel with a load of 90 tons, and an average speed of 29 miles, is 20·8 pounds of coke per mile. The maximum steam-pressure is 120 pounds to the square inch. In the express locomotive in use on the (narrow gauge) London and North-western Railway, the diameter of cylinder is 18 inches, length of stroke, 24 inches, driving-wheel, 8 feet. The amount of heating-surface in the tubes is 2136 feet; in the fire-box, 154; the evaporation equal to 1140 horse-power, the pressure of steam, 120. With reference to the mode of estimating the power of a locomotive, a good authority has the following: 'The high pressure which yields power, and the rapid evaporation which gives the means of applying the power directly to obtain speed, are dependent upon the effect with which heat can be applied to the water in the boiler; and hence the amount of surface exposed by a boiler in any manner to the action of the fire in the furnace or fire-box, or to heat arising from it; that is to say, whether by means of

tubes running through the boiler, and forming flues to the heat from the fire, or by a casing about the fire in the furnace, is the measure of the capability of the engine in respect both of power and speed.' The evaporation of a cubic foot of water per hour is equal, in the ordinary method of calculation, to one horse-power; this being effected by the consumption of from eight to ten pounds of coke. On some branch-lines, a light species of locomotive, with passenger-carriage attached, the whole forming one structure, has been introduced; that constructed by Mr Samuel weighed only twenty-five hundredweights, and conveyed seven passengers at the rate of thirty miles an hour.

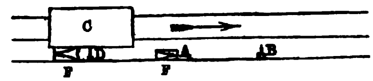
A locomotive is calculated to be capable of running 95,000 miles before requiring repair. The average distance run annually by a locomotive is 30,000, and the deterioration in value is estimated at three-halfpence for each mile run.

In America and Belgium, most lines consist of but one track; British railways, with few exceptions, possess two tracks, suitable for trains going in opposite directions; besides which, there are turn-offs or sidings, at which quick-going trains may pass those of slower motion. At certain convenient points along the line there are station-houses, at which the trains stop to take up and set down passengers, and there is no stoppage at any other place.

The termini of the principal railways are most gigantic concerns, and are complete, not only as regards their facilities for the transmission of passengers and parcels, but for heavy goods. At the Camden station of the London and North-western Company, there are twelve miles of rails laid down in an endless variety of directions. On most of the lines there are slow trains, taking goods and second-class, or an inferior kind of carriages; and fast trains, taking only first and second class carriages; some lines also have mail-trains, which proceed at more than usual speed, and taking only first-class carriages, stop at fewer places by the way.

The usual speed of an ordinary railway-train is from twenty to twenty-five miles an hour, though sometimes it is much more. The mail-train from London to Manchester (188½ miles) usually takes six hours, being at the rate of thirty-one miles; the express from London to Edinburgh by the Great Northern (399½ miles) performs the journey in eleven hours. The speed on continental railways is less than in Britain; in Belgium, for instance, the average speed is 20 miles. High velocities are much more injurious to the permanent way as well as to the engine, than moderate rates of speed. Another point of interest to be noted, is the decrease of tractive power with increase of speed. Thus, an engine proceeding at the rate of 10 miles an hour, may drag 250 tons; while only 28 can be drawn by the same engine if the speed is increased to 30 miles.

The arrangement for carrying on the mail-contract on the chief lines is worthy of notice here. The post-office van is a carriage consisting of two small apartments, one of which is appropriated to the guard, whose duty is to exchange the bags, and the other is fitted up with a table for sorting letters, and holes round the walls for their reception. The manner in which the duties of the clerk and guard are performed in this flying post-office, is strikingly significant of the new order of things introduced by the railway system. Outside the vehicle, a species of net is extended by a hoop, and into this the letter-bags are dropped as the train sweeps onward in its course—the bags which are to be left being at the same time tossed from the window by the guard. The fresh bag of letters being received, is speedily opened, its contents rearranged, and a new bag for next town being made up, is ejected as before at the place of its destination. Self-acting apparatus has been introduced on many of the principal lines, by which the bags are taken up and delivered at the stations without involving either manual labour or the stoppage of the train. 'This apparatus consists of a wooden frame and net attached, shewn in plan A, and an iron



post, B, fixed in the ground at the side of the railway, in a direct line with each other; and a corresponding apparatus affixed to the side of the carriage, C—namely, a projecting arm, D, to support and deliver an envelope with bag or parcels enclosed, into the net, A, which is fitted with conveying guide-lines, F, to receive them. These lines are of great importance, the acute angle being the part in which the envelope is griped.' A folding-net is attached to the side of the carriage, to receive the envelope from the delivery-standard, B.

There are certain advantages in the arrangements of all the railways over common roads, which deserve to be mentioned. Each line, being the property of a private association, is secluded from one end to the other from the intrusion of the public; and therefore no jostling or confusion need take place, either upon entering or leaving the carriages. The rails of one line likewise join those of another, by which means carriages generally proceed onwards, without changing passengers or luggage. A carriage in which passengers take their seats at London can go straight on to Edinburgh or Aberdeen. The extraordinary magnitude of the railway undertakings, has enabled the directors to organise rules which could never be enforced in the irregular scramble of stage-coaching. It is customary to dress the subordinate functionaries on all the lines in a distinctive uniform—each man having his number inscribed in figures on some part of his dress; so that if any one be guilty of incivility or inattention, he can be easily reported to his superiors. There is one pleasing peculiarity in the arrangements which is entitled to the highest commendation: it is the rule that no officer shall, on any account, take a fee from passengers, on pain of instant dismissal. Those who imagine that fees to guards, coachmen, or waiters, are requisite to insure civility, will be surprised to find that railway attendants are infinitely more polite and attentive than their brethren of the coach-conveyances. This in itself gives travelling by railway a great superiority over all other modes of public conveyance. On all the lines, there are waiting-rooms, both for ladies and gentlemen, at the different stations; and at all the important ones, there are refreshment-rooms, where meals stand ready prepared for the passengers.

The arrangements necessitated by the plan, now so general, of booking passengers through from one town to another, passing over different railways, are of a somewhat complicated nature, and deserve notice here. This business is managed by the officials of what is termed the Railway Clearing-house. The committee of management consists of delegates, one from each of the railway companies. The duty of the officials under this committee is to make up from time to time balance-sheets, shewing the state of accounts between the companies working in conjunction. The proceeds are divided among the companies, in proportion to the mileage contributed by each to the common traffic. The rate of payment is generally a matter of arrangement specially entered into between the companies. The data from which the accounts are made up are obtained by what are called 'number-men,' whose duty it is to attend at the junctions, and carefully note the number of the engines, wagons, carriages, &c., passing from one line to another. The number of passengers is also ascertained by the clerks at the various clearing-house stations taking a note of the tickets issued and received; the goods-traffic is ascertained in the same way. Nearly all the important narrow-gauge lines are connected with the Clearing-house, each contributing to its working expenses in

proportion to the amount of the balance which is paid to its credit. Such a system has been productive of great benefit to the public, not only in point of convenience, but from its tendency to equalise and lower the rates of transmission. The principle is, however, capable of much extension, and will erelong, in all probability, be arranged so as to comprehend within its jurisdiction all the railways in the kingdom. It carries on its operations under the protection of a special act.

It only remains for us to notice the *personnel* and the working-stock of a first-class railway company; and to glance at the proportion which the working expenses bear to the general receipts. The following will give an idea of the employment afforded by the London and North-western Railway Company:—2 secretaries; 1 general manager; 3 superintendents; 2 resident engineers; 966 clerks; 3054 porters; 701 police-constables; 738 engine and fire men; 3347 artificers; 1452 labourers—total employed, 10,266. In the collection and delivery of goods and parcels, 253 vans are employed; and in the working of the line, changing carriages at sidings, &c., 612 horses. The extent of Messrs Pickford's establishment for conducting the goods-traffic of the same railway will be seen from the following:—The number of clerks, 234; porters, 438; horses, 396; vans, 82; wagons, 57; drays, 25. The working-stock of the same railway in 1851 was as follows:—Locomotives of all classes, 582; first-class carriages, 586; second do., 564; third, 344; post-office vans, 25; 271 horse-boxes; 249 carriage-trucks; and of guards, break, and parcel vans, 210. The goods-traffic stock consisted of 8195 wagons, 232 sheep-vans. The cost of a locomotive may be taken at £2000; of a first-class carriage, £300 to £350; a second do., £200 to £260; third, £200; horse-boxes, £120 to £150; goods-wagons, £100 to £120; luggage-vans and breaks, £70 to £100; coal-wagons, £60 to £80; sheep and cattle wagons, £100. In regard to the working expenses of railways, we extract the following from a series of useful tables on the subject, embracing all the important railways in the kingdom, given by Mr Chattaway:—For the half-year ending November 1851, it appears that the total expenses were £641,003; and the total receipts from all sources, £1,409,128; the percentage of expenses to receipts being 45·489. The amount expended in maintaining the permanent ways was upwards of £78,000, the percentage to receipts being about 5½; the locomotive expenses upwards of £191,000, the percentage, 13½; for carriage, &c., repairs, £54,000 was spent, being nearly 4 per cent. on the receipts. The charges for the merchandise traffic were nearly £150,000, the percentage to receipts being nearly 10½. The coaching-traffic charges were nearly £93,000, the percentage, 6½. The general charges were £23,482, being more than 1½ per cent. on the receipts. The total working charges were nearly £590,000, making the percentage of expenses to receipts 41·641. To this was added the rates, taxes, and the duty paid to government on passengers—a tax of which the general public is not aware—amounting to £54,221, being nearly 4 per cent. on the receipts.

It is mainly to the reduction of the working expenses of the various railways that the shareholders must look for an increase of dividend. To do this effectually, and yet without compromising the safety of travellers, by impairing the efficiency of the permanent way and the rolling-stock, requires the exercise of great judgment and prudence. It is indeed in this department that railway management is at once tested.

In concluding our remarks on railways, we might enlarge upon the social and political benefits conferred on the community by their general introduction; but tempting as the theme is, we must refrain, contenting ourselves with the following extract, which, in few words, contains a summary of the advantages derived from them socially, politically, and commercially. 'Increased government revenue—increased value of all property—increased cultivation and produce, and extension of manufactures—increased accommodation to all classes for intercommunication—diminished cost of all descriptions of goods to consumers, and increased consumption by accession of numbers—diminished risks of war and insurrection, with increased powers for their suppression—a measure of universal benefit, without a drawback or objection, if selected and carried out under due provisions, with judgment and discretion.' The reader anxious to go more fully into the details of the railway system may consult the following works with advantage:—*Railways, their Capital and Dividends*, by E. D. Chattaway (Weale); *Railways, and Sketches of the Construction and Material*, by R. M. Stephenson (Weale); *Our Iron Roads*, by F. S. Williams (Cooke); and Dr Lardner's *Railway Economy*.

Atmospheric Railways.

If a smooth and straight metal tube be provided at one end with an air-tight piston, and the contained air be extracted at the other end, the piston, on being let go, will traverse the tube from end to end, being, as it were, forcibly driven by some unseen agency. This agency is the weight or pressure of the atmosphere, which, acting upon the piston, drives it along with a force proportionate to the vacuum formed in the tube and the number of square inches of the piston's surface. This, then, is the principle of the atmospheric railway.

If the reader will suppose the tube large enough to admit a train of carriages, the train being attached to the piston, he will have a good idea of the atmospheric railway, as first proposed to be established between London and Brighton. This mode of travelling in a continuous tunnel not possessing many charms to ordinary travellers, excepting that of novelty, the scheme, as might be supposed, did not succeed; but the idea being a good one, many engineers and men of science directed their attention to the subject. The first evident improvement to be made was to have the carriages *external*, and connected with the piston by some contrivance sliding along a slit or opening made in the upper side of the tube. Messrs Clegg and Samuda patented improvements, which were first tried experimentally at Wormwood Scrubbs, on a portion of the West London Railway; and these proving successful, were adopted by the Dublin and Kingstown Railway on that part of their line between Kingstown and Dalkey, a distance of about one mile and three-quarters. This line is much inclined; the carriages descend by their own gravity, and are propelled up the incline by the atmospheric agency. This first application of the atmospheric principle is still in successful operation. It was subsequently tried by the London and Brighton and South Devon companies; but difficulties in the working ultimately induced the directors to abandon the principle, and adopt the usual system. Although many of our first engineers expressed their confidence in the atmospheric principle, nevertheless it has failed in establishing itself as an economical mode of locomotion. Its 'weak point' is doubtless the valve, and the difficulty of closing it again air-tight after each passage of a train.

Electric Telegraph.

Astonishing as the rapidity of railway transit may appear, it is not for an instant to be compared with that of the Electric Telegraph. This wonderful apparatus is now appended to every railway of importance, both for the purpose of conveying messages in connection with the working of the line, and as a means of correspondence for the public. Telegraphs so set in motion were invented by Cooke and Wheatstone about the year 1837, but have since undergone numerous modifications and improvements by Morse, Bain, Brett, Little, and others. As explained under ELECTRO-MAGNETISM, the invention depends upon the principle, that an electric

current can pass along a conducting-wire to any distance, and be made to move magnetic needles at any part of its course—these needles indicating or signaling according to some predetermined arrangement. The essential parts of the mechanism are, the *conducting wire* or wires, the *battery* which generates the electric current, the *signaling apparatus*, and the *mechanism for making and breaking the metallic contact* that completes the circle.

We shall briefly indicate the various steps in the process. The forms of batteries used for generating the electric current are very numerous; the one most generally employed on the Electric Telegraph Company's lines is that arranged by Mr Cooke, and known as the *sand battery*. It is on the principle of Wollaston's trough, with plates of copper and zinc, the spaces between being filled with dry and clean sand. To set it in operation, the sand is moistened with sulphuric acid. This form of battery possesses many advantages, requiring little attention, and remaining longer in action than the *wet battery*. In some telegraphs the current is produced by magneto-electric machines (see ELECTRICITY).

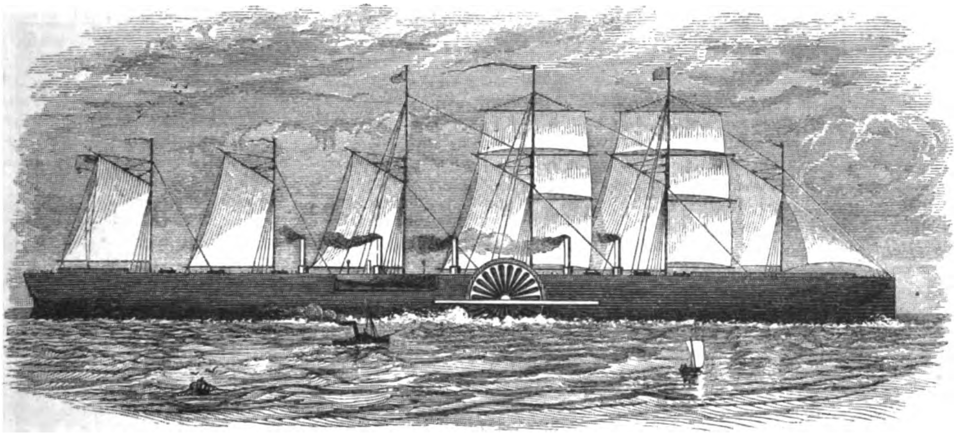
In this country, the telegraphic wires are suspended between a series of posts fixed in the ground by the side of the railway. In insulating the wires from the poles, a variety of methods have been introduced; the aim in all is to keep the points of contact dry. The most improved insulator is the green glass hollow cup. This is placed in an inverted position, and the support by which it is connected with the post is bent upwards, and fastened to the interior top of the cup by proper cement. The wire is passed round the exterior of the cup. To prevent corrosion, galvanised wire is generally used. In carrying the wires along the streets, they are placed in iron pipes, and insulated by a coating of gutta-percha; the tunnel wires are also insulated by this material. The electrical circuit is completed by connecting the extreme ends of the wires with plates of copper sunk some three or four feet in the ground. The earth thus forms one half of the circuit, the wires stretching from pole to pole the other. In submarine telegraphs, the wires, each coated separately with gutta-percha, are enclosed in a strong cable formed of spun-yarn and galvanised iron-wire.

The Signaling Apparatus.—A current of electricity being once established, there are various ways in which it may be made to produce a set of motions at will, at any part of the circuit. The *needle* signal is the one generally employed in this country. As has been already explained under ELECTRO-MAGNETISM, when a magnet, balanced on a pivot, is placed alongside the conducting-wire of a galvanic circuit, it turns at right angles to the wire whenever the current is made to pass; and the deflection is to the right or to the left according to the direction of the current along the wire. Two needles, then, are fixed on one axis, the one in front of a dial-plate like that of a clock, the other inside the frame; and they are so arranged that the needle outside, when undisturbed, remains perpendicular. A coil of the conducting-wire is now disposed round the interior needle, and the current being sent through the coil in one direction, the needles, both interior and exterior, are deflected, say to the right, and on reversing the current, the deflection is changed to the left. The contrivance by which the direction of the electric current is changed, is called a *commutator*, and is too complex for mere verbal description. It is sufficient to say, that by the simple motions of a handle, making and breaking contact between a number of metallic points, a succession of reversals of the current, and consequent alternations of the needle from right to left, and from left to right, may be effected with great rapidity.

As the movement of the handle may be made in London and the deflections of the needle take place in Edinburgh, it is evident that by agreeing to affix certain meanings to the deflections, a message may be conveyed instantaneously from the one place to the other. By fixing, for instance, that a motion to the right shall signify A, one to the left B, two to the right in rapid succession C, &c., the electric current may be made to spell any word that is wanted. In order to avoid too many repetitions of the deflections, two needles are generally employed. In the United States, the telegraph most in use is Morse's, in which the pulsations of the current guide the oscillations of a lever with a pencil attached, so as to make interrupted tracings on a moving strip of paper.

The decomposing powers of electricity are taken advantage of to produce an electric telegraph which prints its own messages. In Bain's printing telegraph, bands of paper, moistened with a mixture of sulphuric acid and prussiate of potash, are interposed in the electric circuit; whenever the current passes, the solution is decomposed, and a blue mark made. The alphabet is composed of a combination of short and long marks, produced respectively by instantaneous currents, and by others of short duration. 'These currents are sometimes sent by hand by mere making of contact; at other times, short and long holes are punched in a dry paper band, and this is drawn by clock-work between the metal point and cylinder which closes the circuit, and thus the current is cut off, when the sound part of the paper intervenes and passes, when the presence of a hole allows the part to touch the cylinder, and complete the circuit. The moist paper receiving the spots is made to move on at a like rate.' In House's and in Brett's printing telegraphs, the communications are impressed, not in cipher, but in common letter-press. A set of keys, similar to those of a pianoforte, are marked with the letters of the alphabet; and by pressing down the key marked D, for example, the letter D on a wheel at a distant station is brought into a position where it is impressed on a scroll of paper. Mr Brett states that an experienced clerk could manipulate upon the key-board upwards of 150 letters per minute. A still more wonderful form of printing telegraph is that of Bakewell, in which a positive facsimile of the message which the sender writes down at one end of the line is produced at the other. The decomposing powers of electricity are taken advantage of in this form, the moistened paper band being used; but the messages are written by means of a varnish on a tin foil, which is interposed between the point and the cylinder. The interruptions caused by the varnish-writing, break the electric circuit in those places, and cause a cessation of marking while the style or point is passing over each letter. As the style traverses several times over each letter or line of writing, the successions of interruptions produce an exact copy of what is originally written on the tin foil; the copy at the other end being written in a pale colour, on a ground of closely drawn blue lines. The cylinder on which the varnish-written message is wound, is made to revolve at the same rate as the cylinder at the other end of the line which receives the moistened paper.

The extension of the electric telegraph, has been yet more rapid than that of railways. Throughout Europe and North America, a net-work of these magic wires already unites all the chief towns, and ramifications are rapidly extending in all directions. Nor is the ocean an insuperable barrier, as in the case of railway-communication. The submarine cable unites Ireland to Britain, and Britain to the continent of Europe; Spezzia in Piedmont will soon be joined to Bona in Africa, by way of Corsica and Sardinia; and there is every prospect that, before a year elapses, a cable will be laid from Ireland to St John's in Newfoundland, which will complete the communication between the Old World and the New.



The *Great Eastern* Ocean Ship—screw, paddle, and sail.

MARITIME CONVEYANCE.

THE instruments of maritime conveyance are *ships*—a term which, though commonly applied to decked vessels only, may be made to include every species of craft, from the rude canoe of the savage to the three-decked man-of-war.* Their construction and equipment, their navigation and management when afloat, the building of docks and harbours for their reception, the erection of light-houses and beacons for their guidance; in fact, the whole science by which man is enabled to traverse the ocean, and bring the most distant regions, as it were, into local proximity, is one of superlative interest, and especially so to the inhabitants of an insular country like Britain. To a brief exposition of its leading features, as above indicated, we intend to devote the present sheet.

A notice of the details connected with the arrangement and construction of harbours, piers, docks, &c., will be found in the number on CIVIL ENGINEERING.

SHIPS.

Of the early history of ship-architecture little can be said of any importance. The buoyant property of water, particularly that of the sea, must have been soon observed by mankind; and therefore, beginning with rude skiffs and canoes, they would in time acquire sufficient experience and skill to form vessels of a larger size, and to guide them in the required direction by means of a rudder and sails. The cultivated nations of antiquity—Egyptians, Phœnicians, Carthaginians, and others—possessed ships for commerce and war, some of which were of large dimensions, and were moved either by oars or by the action of the wind on sails. But of these early vessels, as well as of those now employed by half-civilised nations, it is unnecessary here to speak; we proceed rather to notice the construction and character of ships formed according to the principles of modern and improved science.

The nicest and most difficult operation in ship-building consists in first forming a draught or model of the proposed vessel, or, as we may call it, the *plan* which the mechanics are to adopt and follow out. In forming this plan, the designer is governed by a consideration of the precise object to be attained. There are two classes of vessels—ships-of-war and merchantmen—and each must possess certain qualifications. In a ship-of-war the great object is speed, with ease of movement, and capacity to accommodate her crew, and to carry a sufficient weight of guns, stores, and provisions. One point, moreover, is especially to be looked to; this is, that the ship float high enough above water to run no risk of receiving waves or seas in her lower ports during action, when these holes must be necessarily open. In order to secure this, the constructer makes an estimate of the whole weight of the ship, including body, spars, armament, men, and munitions, and must so model the bottom that it will have displaced an equal weight of water when arrived at the desired depth. In the case of merchantmen, the primary consideration is to attain the greatest capacity to carry cargo, combined, as far as possible, with safe and easy movements and rapid sailing.

The English excel in ship-building, but in some respects they are outdone by the Americans, whose packet-ships carry enormous weights, while they are noted for their speed. Among the admitted and well-established principles of construction is the leading one, that the greatest breadth must always be before the centre, and consequently the *bow* or front be more blunt than the *stern* or hinder part. Abstractly, it would seem most important that the bow should be the sharpest, so as to cleave the water with the least possible resistance; but experience has proved that it is far more essential to facilitate the escape of the displaced water along the side of the vessel; for when once a passage is opened for the ship, the fluid tends to reunite behind the point of greatest breadth, where, instead of offering resistance, it presses the ship

* The etymology of the word shews what the thing was in its origin. *Ship* is only another form of the word *skiff* (Ger. *schiff*, a ship), and is evidently from the root of the verbs to *shape*, and to *scoop*, or 'hollow out.' The original 'ship,' then, was simply a tree 'scooped' out.

'orward, and fills up the space constantly opening behind ier. The principle is evident in the form of the duck ind other aquatic animals, which are uniformly broadest n front, and gradually diminish to the tail. As it is, hen, less essential that a ship should be sharp forward han aft, there is a further advantage in having the bow 'ull towards the edge, that it may check her in descending into the waves, not abruptly, but gently—pitching, or rising and falling endwise, being the most dangerous o hull and spars of all a vessel's movements. Though harpness towards the stern-post is vitally essential to ast sailing, yet care must be taken to leave the buttock 'ull towards the surface, in order to check the stern gently in descending, and when scudding before a gale, o lift it in timely season on the arrival of a sea. To hit he exact mean in these respects, so as not to retard the ailing on the one hand, nor endanger the ship on the other, requires all the skill of the architect.

There must, likewise, be a due correspondence between he general bulk of the vessel and its length and breadth: he whole must be properly proportioned. If unduly ong, speed may be gained, but there is a difficulty of urning, and also of rising to escape the breakings of the ea; long ships, therefore, are apt to roll and to cut hrough waves, instead of breasting them, by which their afety is perilled. When a ship is unduly short for its general bulk, it is apt to pitch, which is equally dangerous; ence the greatest care is required to proportion the arious dimensions.

As many of the requirements in the construction of a hip do not harmonise with each other, the skill of the naval architect is shewn in duly proportioning them to one another, ascertaining that which is chiefly desiderated, and carrying this out without impairing the efficiency of he others. The following is a description of the peculiarities of a form of ship which is considered to meet all he usual requirements. 'The body of a ship above its niddle has nearly the form of a portion of a hollow cylinder, with its axis horizontal, and its convex side lownwards. Above the surface of the water on which it loats, the sides are curved, so as at the head to have, in a horizontal direction, the form of a Gothic arch, more or less acute. The breadth diminishes gradually towards he stern, which above water is either a plane surface nearly perpendicular to the ship's length, or, according to Sir Robert Seppings's construction, curved so as to have a horizontal section nearly the form of a semi-ellipse. Below the surface of the water, the body of the ship is curved in a horizontal direction towards the head and stern, so as to terminate at those places in angles which diminish from that surface downwards; and thus a vertical section taken perpendicularly to the length of he ship, at some distance from the middle towards either extremity, presents on each side the form of a curve of contrary flexure.' The researches and experiments of Mr Scott Russell on the 'form of least resistance at high velocity,' are considered by authorities to have an important practical bearing on the form and motion of vessels.

In commencing to design a ship, the first duty of the architect is to ascertain her displacement (see HYDROSTATICS), or the weight of water which she displaces, which is that of the ship itself. From this her general proportions are deduced, the bulk being in proportion to he length, breadth, and depth. These being known, the nidship section, or transverse vertical section, at its widest part, is next decided on; the load-water section, or horizontal section at the surface of the water, being he next point claiming attention. Other vertical transverse sections are also laid down, at parts of the ength where the form varies from that of the midship section, together with the depth below the water-line. These points being settled, a series of drawings on a small scale are made. They are generally three in number; one shews the vessel as cut in two, from stem to stern, and is called the 'sheer-plan;' the second is a plan taken horizontally at the line of greatest breadth, and is termed the 'half-breadth plan;' the third shews the midship section, and is termed the 'body-plan.' From these drawings enlarged drawings are made, in what is called the 'drawing-floor' or 'mould-loft,' to the full size, the lines being laid down on the floor. The exact shape and position of the timbers are here shewn to guide the workman in all the details.

All essential preliminaries being settled, the ship is begun to be constructed; and this is always done in the yard of a ship-builder, close by the water's edge. The wood considered to be best adapted for ship-building is oak, pine, teak, elm, or beech; and whichever is employed, it requires to be strong, well seasoned, and dry; the greater part, likewise, should be bent or crooked, to suit the curves and angularities in the structure; and for this end, growing timber is often constrained to assume particular forms. The *keel*, which is the lowest part of the vessel, and corresponds to the backbone of an animal, from which the ribs or *timbers* spring, is formed and laid first on a slip and blocks set for the purpose. As the framework proceeds, all parts are firmly bolted and riveted together, and the whole is finally covered with the planking in even lines from bow to stern. When it is necessary to bend a plank for either the bow or stern, it is heated by steam, and then forced into its place by screws and levers. The planks are fastened to the ribs by *treenails*, or wooden pins, and the plan is followed of allowing a seam or space between each plank, which is filled up or *calked* with oakum, and the whole is smeared with pitch. In some instances, the bottom is further secured by sheathing it in sheets of copper. Meanwhile, the interior beams and partitions have been placed; and when duly prepared, the vessel is *launched*, or shot into the water by an easy movement, down the inclined plane on which it rests. After launching, the rudder or *helm* is shipped. The rudder is a wooden apparatus placed at the stern of the ship, a large portion being in the water; and by means of it, the vessel is steered and turned about at pleasure. The steering part is on deck, and consists either of a simple lever, called the *tiller*, or of a wheel placed perpendicularly, and connected with the tiller by chains and pulleys. The principle on which the rudder acts is very simple: the object is to turn the vessel; and to whatever side the inclination is to be made, the rudder is caused to present an obstacle to the water in that direction.

The masts of the vessel are now set; and the *spars*—comprehending the bowsprit and yards, and also the rigging—are attached. The spars of a ship are not abandoned to their own unsupported strength, but are sustained by what is called the *standing-rigging*, which consists of strong well-spun ropes, or, in some recent instances, of iron wire twisted into strands of the requisite thickness. Besides this, there is the *running-rigging*, which consists of the tacks and sheets that serve to spread the sails, the halliards, traces, lifts, clew-lines, and all other ropes used in making, taking in, or manœuvring the sails. In the construction of both hull and rigging there is a vast amount of bolting, nailing, splicing, and so forth, much of which is likely to be now superseded by the use of Jeffrey's marine glue—a substance of such tenacity that planks joined by it have been found to give way invariably in the solid wood, and not at the junction. Masts marine-glued, and without hoop or bolt, have been tried, and, after the exposure of a tropical voyage, have returned sound and strong as on the day they were constructed. Indeed, so invincible is the tenacity of this compound, that the possibility of constructing a hull without bolt or treenail has been soberly asserted.

The sails of a ship are sheets of canvas bent to the yards, and fore-and-aft sails traversing on stays or bent to gaffs. Let us proceed to describe an entire suite, beginning forward, and referring to the subsequent

figures :—On the extremity of the bowsprit is the *flying-jib*, a three-cornered sail, which goes from the end of its boom upward along its stay, leading to the foretop-gallant-mast-head, and confined to the stay by rings of wood or iron, called the *hanks*. It is hoisted by means of the halliard; hauled down by a down-haul; and when up, is trimmed to hold the wind by a sheet or rope leading to the forecastle. The *jib*, which leads from its boom to the foretop-mast-head, is of similar form, and so is the *foretop-mast-stay-sail*, running from the bowsprit end towards the mast-head. On the fore-mast we have the *fore-sail*, bent to the fore-yard, and spread at the foot by means of tacks and sheets; above it, the *foretop-sail*, bent to the top-sail-yard, by means of which it is hoisted aloft, while its lower corners are spread to the extremities of the fore-yard; next the *top-gallant-sail*, bent to its yard, and sheeting home to the top-sail-yard; and so with the *royal* and *sky-sail*. All these sails are turned at pleasure, to be presented to the wind, by means of braces attached to their yard-arm, and leading to the mainmast. The mainmast is furnished with a similar suite of sails, somewhat larger; the mizzen-mast also, though smaller than either, instead of a square-sail on the lower part of the mast, has a *gaff-sail*, hoisting up or down abaft the mast. Some ships have similar gaff-sails on the fore and main masts, which are found of great use in gales of wind, as a substitute for storm stay-sails. Most carry, also, light stay-sails between the masts; but they are very trouble-some. *Studding-sails*, spread beyond the square-sails like wings, are found useful when going before the wind. The perfection of equipping a ship with spars, rigging, and sails, consists in so disposing them, that in a whole or full sail breeze the centre of effort of all the sails will be in the same line with the ship's centre of rotation; or that the efforts of the forward and after sails to turn the ship will be exactly balanced, as not to require any continued assistance from the rudder in either direction.

Such is a brief outline of the construction of a common decked vessel as regards hull and rigging. It must be remembered, however, that different modes are adopted according to the kind of service for which the craft is intended, and that general improvements are occasionally being made in naval architecture. Thus, independently of a difference in material, some arrange the timbers or framework in such a manner that they shall form the main strength of the vessel; while others, following a cheaper and less scientific course, plant the timbers perpendicularly and sparsely, thereby throwing a great, if not the greater, portion of the strain on the outer planking. Again, much depends on the securing of the masts, which, when under press of canvas, act as powerful levers on the parts of the hull to which they are attached. Instead of resting these only upon steps, strong platforms, which diffuse the pressure on all sides, are now generally used, and by this means a fertile source of leakage extinguished. Round sterns, which can be constructed with all the strength of the bow, are now also preferred to the old square and massive but weak stern; and further, the breadth of beam, which adds stability to the whole fabric, has of late been considerably increased.

The principal ship-building ports in Britain—laying aside consideration of the government dock-yards—are London, Sunderland, Newcastle, Liverpool, Hull, Greenock, Glasgow, Aberdeen, Yarmouth, &c. With respect to the classification of British vessels, Mr M'Culloch remarks: 'Until very recently, ships, how much soever they might differ in other respects, were classified at Lloyd's (the office of the Society of Under-writers, and great centre of shipping affairs) with reference solely to their age and the place where they were built. Thus, supposing two ships were launched about the same time in the Thames, the Wear, or anywhere else, they were enrolled together in the *highest* class in Lloyd's Register, and stood there for a certain number of years, how different soever they might have originally been, or how different soever they might afterwards become! And underwriters, thus seeing them standing together, and having no other test of goodness to which to refer, insured and employed the one on the same terms as the other! It is unnecessary to dwell on the preposterous absurdity of such a system. Practically, it operated as a high bounty on the building of defective, or what is called *slop-built* ships; and there can be no doubt that it tended materially to depreciate the character of our mercantile marine, and to multiply shipwrecks to a frightful extent. We are therefore glad to state that a new system of classification has been adopted, by which the place of vessels on the register will be made to depend, not on their age, or the port where they were built, but upon their actual condition.' The several classes are marked by the letters A, Æ, E, and I, which have reference to the state of the hull; and by figures which indicate the condition of the stores and equip-ment. Thus, 10 A1 denotes a ten-years' ship of the first description of the first-class, with stores well and sufficiently found. Steam-ships are similarly classified, but require to be surveyed *twice a year*.

With respect to the methods in use for ascertaining the tonnage of a ship, or, in other words, her capability for stowing and carrying of cargo—from the discussion recently entered into on the subject, there seems great reason to desire the establishment of a scientific principle by which this could be easily and uniformly obtained, the whole subject being evidently surrounded with diffi-culties. Thus, in the act of 1854, the tonnage admea-surement is based on the internal capacity of the vessel; but the system is so complicated, as to render the practi-cal operation whereby the results are obtained a mystery unintelligible to everybody excepting those who make it a professional study. The consequence is, that this, the legal system of admeasurement, is rarely adopted as 'the base of mercantile contracts for the purchasing and building of ships;' but the old law of 1773, known as 'builders' measurement,' with all its glaring defects, is that generally followed. The following is the law here alluded to: 'The length shall be taken in a straight line along the rabbet of the keel of the ship, from the back of the main stern-post to a perpendicular line from the fore-port of the main stem, under the bowsprit; from which subtracting three-fifths of the breadth, the re-mainder shall be esteemed the just length of the keel to find the tonnage; and the breadth shall be taken from the outside of the outside plank in the broadest place of the ship, be it either above or below the main walls, exclusive of all manner of doubling planks that may be wrought upon the sides of the ship; then multiplying the length of the keel by the breadth so taken, and the product by half the breadth, and dividing the whole by ninety-four, the quotient shall be deemed the true con-tents of the tonnage.' The term 'tonnage' is theoretic-ally meant to convey the amount of sea-water which the interior capacity would contain. Under the new law, it 'has no reference whatever to the *tons-weight* which a ship will carry; but means that a ship of given tonnage has the available internal capacity of 100 cubic feet for each ton of *nominal tonnage*.'

The impetus given by the rivalry of steam-navigation has led to the construction of sailing-ships possessing surprising power and speed. Great Britain and America are honourably competing for superiority in the construc-tion of 'clippers' having these properties; and every year adds to the number of successful examples—such as the *Sovereign of the Seas* (2420 tons), in 1853; the *Tayleur* iron sailing-ship (2500 tons), in the same year; the *Great Republic* (3400 tons), in 1854; the *Donald M'Kay* (2590 tons), in 1855; and many others, British and American.

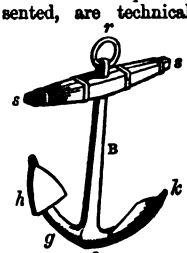
Cables, Anchors, Lightning-conductors, and Buoys.

By the substitution of iron link for hemp cables, due to the late Sir Samuel Brown, an important benefit was

bestowed on the shipping community. The old hemp-cables were liable to rapid decay, and to being cut on rocky bottoms, or suddenly snapped by the pitching of the vessel. The invention of the chain-cable has been characterised by the highest authority as a 'vast improvement'—one of 'the greatest effected for the shipping interests, and the preservation of life and property.'

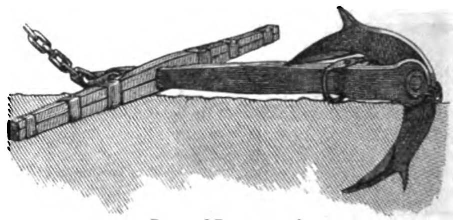
The retarding apparatus of the vessel consists of heavy iron instruments, called anchors, of which each vessel has usually more than one. Large ships carry the following suite of anchors: 1. The *sheet*-anchor, which is the largest, and only used in the case of violent storms; 2. Two bower-anchors—namely, the *best bower* and *small bower*, so called from their situation at the bows; 3. The *stream*-anchor, the *kedge*, and *grappling* or *grapnel*. The last three are often used for moving the ship from place to place in a harbour or river. Each anchor is let down by a strong cable of iron or rope, and is lifted by means of the windlass placed on deck. To the cable, when in the water, a *buoy* or floating object may be attached, to shew where the anchor has been let down; and to save time, or in an emergency, the anchor and cable are sometimes left, while the vessel proceeds, the buoy serving to point out where the anchor may be recovered. The anchor is said to be *a-peak* when the cable is perpendicular between the hawse and the anchor; it is said to *come home* when it does not hold the ship; it is said to be *foul* when the cable gets hitched about the flukes. *Riding at anchor* is the state of the vessel when moored or fixed by the anchor; *dropping* or *casting anchor* is letting it down into the sea; *weighing anchor* is raising it from the bottom.

The several parts of a common anchor, here represented, are technically designated as follows: The



straight bar B, to which the cable is attached, is called the *shank; r*, the *ring;* the cross bar *ss*, fixed at the free extremity of the shank, the *stock;* the upper end of the shank, the *small round;* the extremity c, where the shank and arms unite, is called the *crown;* the angle formed by the arms and the shank is termed the *throat*, and generally stands about 56°. The arms consist of three parts—the *blade* (*g*), the *palm* (*h*), and the *bill* (*k*). The palm or fluke is made of a flat triangular shape, the apex of which is prolonged so as to form the bill or peak. However large and ponderous, anchors are all formed of bar-iron, welded and wrought together by hand-hammering. Their fabrication, which is extensively carried on in Britain, requires great skill and care.

In addition to the common anchor represented above, there are various other forms in use, each laying claim to some peculiar superiority. Thus, the grapnel has three or four arms instead of two; the mushroom anchor (so called from its shape), much used in the East Indies, has an entire holding edge, being shaped like a mushroom or bowl. When we consider the importance of the duty an anchor has to perform, and the value of the lives and property dependent for their safety upon its capability to perform this under all circumstances, we can easily understand the anxious endeavours of inventors to contrive a form which combines at once strength to resist great shocks and strains, and a facility to take and retain hold of the anchorage-ground. Amongst those who have directed their attention to this important part of naval mechanism, special mention should be made of Lieutenant Rogers and the Messrs Porter—the forms of anchor introduced by them have been proved to be great improvements on the old. Lieutenant Rogers is the patentee of three forms, two of which have one arm only, the third has two. The peculiarly distinctive feature of these is the employment of a hollow iron shank, by which, with less material than in a solid one, a greater strength is obtained. The anchor considered by the jury to be the best, at the government trial at Sheerness, was that on Porters' patent principle, modified by Mr Trotman, to which we have already alluded, and which, from its novelty and decided efficiency, is worthy of brief notice here.



Porters' Patent Anchor.

The anchor is formed in two distinct parts, the arms separate from the shank. The part forming the arms is made in one piece, so that no crossing or welding is required. The second peculiarity is the attaching of the curved arms to the shank by means of a strong bolt. To admit of this, the end of the shank is made forked, and the piece forming the arms being inserted between the two projections, the bolt passes through all three. In this way, the arms are not held fixed in one position, but allowed to vibrate on the bolt. The third, and what may be called the distinguishing peculiarity, is the adaptation of projecting horns or spurs to the back of the flukes, or, more properly, at the back of the arms, a little above the fluke. It is upon these spurs or horns that the peculiar penetrating power of the anchor depends. When first canted, it rests upon the stock, the extremity of the shank, and the horn or spur; the horn acting as a fulcrum, the strain upon the cable brings down the point of the fluke to which it is attached. This strain continuing, the arms move in the cheeks of the shank until the tip of the upper fluke presses down upon the upper side of the shank. The position of penetration of the lower fluke being thus obtained, the effect of the continued strain is to cause it to enter the ground. When entered to its full depth, the shank lies flat out parallel to the ground, while the upper fluke is brought close to its upper side. Thus, while the strain is acting upon the anchor, the major portion of the resistance is removed from the bolt on which the arms vibrate, and transferred to the part on which the upper fluke presses. By this arrangement the strain is divided more equably, the leverage brought nearer to the ring, and the anchor thus calculated to resist the various shocks and strains to which it is subjected.

A most important adjunct to ships is an efficient system of lightning-conductors. Under the old system, a small chain or rope of wire was temporarily applied to the mast or rigging; but the peculiar circumstances under which ships are necessarily placed, prevented it from being efficient. The new system introduced by Sir W. Snow Harris of Plymouth, has been eminently successful, and is being largely introduced. The following is a description of the principle and mode of carrying it out: 'Sir W. Snow Harris conceived the idea of making capacious metallic conductors an integral portion of the masts and hull of the vessel, so as to bring the general fabric into that perfect conducting or non-resisting state it would assume in respect of the matter of lightning, supposing the whole mass to be metallic throughout. This he has effected by incorporating with the masts and hull a series of copper plates, so arranged as to meet all the varying conditions of the spars, and so tied together, that an electrical discharge, striking upon any part of the vessel, cannot enter upon any circuit of which the conductors do not form a part, and thus the ship is preserved from the effects of lightning

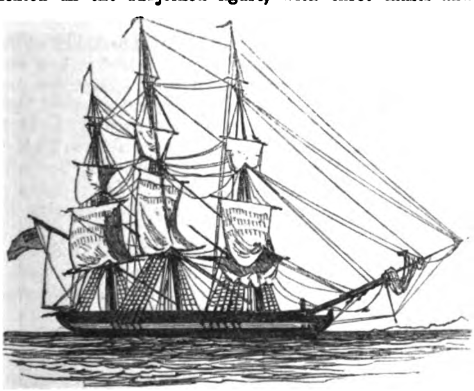
at all times and under all circumstances, without the officers and crews being in any way concerned in the matter.'

Buoys are vessels either formed of wood, cork, or some light substance, moored or anchored so as to float over a certain spot, in order to indicate the situation of a shoal or sand-bank, and thus mark out the course which the ship ought to follow; or they may be constructed of large blocks of wood, clamped with iron, and furnished with rings, to which vessels may moor themselves in rivers or in harbours. When used for the former purpose, they are usually hollow vessels, barrel-built, in the form of a cone, of large dimensions, so that they may be seen at a distance, and generally painted of some particular colour, that they may be more readily distinguished from one another. Mooring-buoys, on the other hand, are generally solid blocks, kept in their places by heavy anchors or sunken weights. As these are liable to be dragged, various methods of secure fixing have been proposed, but none with the same likelihood of success as the 'screw pile' of Mr Mitchell, to be hereafter described.

Referring to NAVAL AND MILITARY ORGANISATION for an account of ships-of-war, we proceed to describe

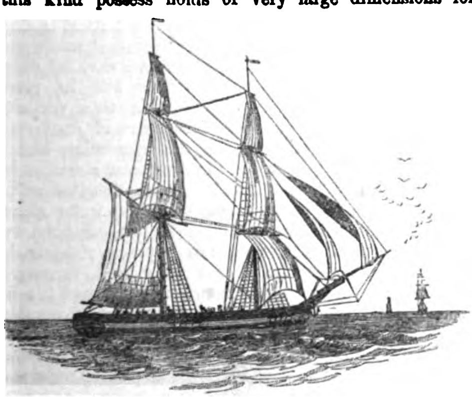
Merchant Sailing-vessels.

Vessels employed in trade, or merchantmen, are of numerous sizes, shapes, and modes of rigging—these depending not merely on the peculiar trade for which they are destined, but on the taste and whims of the owners. The largest is the ship-proper, as represented in the subjoined figure, with three masts and



Merchant-ship.

square sails, but having only an upper deck. Vessels of this kind possess holds of very large dimensions for



Brig.

stowing goods, and their burden is from 1000 to 1500 tons. When destined for long voyages, and in good service, as they generally are, order and discipline are maintained on board with almost as much severity as in the regular navy. The ships employed in the China and East India trade are the largest belonging to this country; those in the West India trade rank next; then the whale-ships, those in the Baltic and Canada trade, the Mediterranean trade, the coal and general coasting trade; and so on in descending gradation.

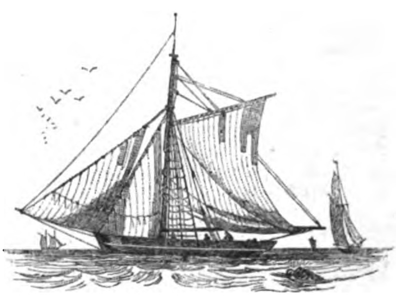
Next beneath the class of ships is that of *brigs*. A brig, of which we here present a sketch, has only two masts, but it possesses square rigging, like a ship. Brigs are handsome and roomy vessels, varying from 400 to 800 tons burden.

With brigs, square rigging terminates, and we now come to classes of vessels in which the rigging is of a different character. At the head of these stands the *schooner*, a vessel with two masts, and capable of carrying a large press of canvass. A schooner is in general

Schooner.

sharp built, with masts of considerable height, and with small topmasts and fore-and-aft sails. The rigging, however, is various, though normally as above represented.

Vessels possessing only one mast are either *sloops* or *cutters*, both distinguished by their tall mast and



Sloop.

extremely large mainsail, which projects beyond the stern. Sloops are chiefly engaged as coasting-traders, and are of all burdens, from 100 to 500 tons. The class of sloops employed to carry goods and passengers between distant ports are ordinarily styled *smacks*. There are schooners and sloops of war carrying from ten to twenty guns; they are generally employed in the custom-house service, and adapted for quick sailing.

A *lugger* is a small kind of vessel, but carrying three masts and a running-bowsprit, with sails of the form called lug-sails. A *brigantine* is a brig which can be either sailed or rowed. A *xebec* is a light swift-sailing vessel, of three masts, and a long prow, peculiar to the ports of the Mediterranean. A *galley* is another vessel peculiar to the ports of the Mediterranean; it is low built, and carries two masts, but depends chiefly on

being rowed with oars; condemned criminals are often sent as a punishment to row these galleys. A *yacht* is a small vessel designed either for state or pleasure. America has recently contested with Great Britain the honour of producing yachts having a speed far exceeding any before known. All the preceding classes of vessels possess decks. Small open vessels, not possessing the accommodation of a deck, are of the class of *boats*, of which there are many varieties—as the long-boat, pinnace, wherry, gig, barge, and so forth. Boats are mostly built with the side-planks lapping over one another; and this, which is called being *clinker-built*, gives them greater buoyancy and strength than if built in the manner of ships.

In every class of merchant-vessels the prime object is to accommodate as large a quantity of goods as possible, and therefore comparatively little space is occupied with accommodation for either the captain or his crew. If the cargo be light, such as cotton, *ballast* is required to be put on board; this consists of sand, shingle, or any other heavy material, which is placed lowest in the hold, in order to balance the vessel, and give it due hold of the water. In the royal navy, iron ballast alone is used, in pigs of nearly three hundredweights. This has the advantage of lying in small compass; but in consequence of its great weight, it tends to give excess of stability, which renders the vessel uneasy from the suddenness of the motion. This defect is remedied by *winging* the ballast, whereby its centre of gravity is raised. For the like reason, in stowing the ballast, it is tapered to a point at the fore and after extremities. Iron ballast, from its greater cleanliness, is more healthy for the crew than that of other materials. When a ship has no other loading, she is said to be *in ballast*. In stowing cargo, care is taken to preserve the *trim* of the vessel—that is, to keep it upright, and also equally balanced fore and aft. The connection between the motions of a ship and her stowage (whether of ballast or cargo) has not, however, been sufficiently analysed to lead to the discovery of any direct rule on this very important point.

Merchant Steam-vessels.

To Scotland is due the honour of having solved the problem of steam-navigation, although America was the first to prove the commercial advantage of the system. A few unsuccessful attempts had been made in earlier years in England and France; but the real start to steam-navigation was given in Dumfriesshire. Mr Patrick Miller, a banker of Edinburgh, who had a country residence at Dalswinton in Nithsdale, after much speculation on the possibility of navigating a vessel without oars or sails, prepared in 1787 a small triple boat, having rotary paddles in the two interspaces, driven by a crank worked by four men. Mr Taylor, preceptor to Mr Miller's sons, suggested a trial of steam-power instead of manual power; and it was then agreed that a new boat should be fitted with a steam-engine under Taylor's superintendence, by William Symington, an ingenious mechanic: the engine to be made by George Watt, brassfounder of Edinburgh. All this being accomplished, the first steam-voyage was made on a small lake at Dalswinton, on the 14th of October 1788. In this instance, the steam-engine worked *one* paddle in the interspace of a twin-boat. On Christmas-day 1789, another steam-boat was propelled, at the rate of seven miles an hour, on the Forth and Clyde Canal; it was made for Mr Miller, was sixty feet long, and was fitted with an engine made under Symington's care at Carron. As a commercial speculation, it was abandoned, through fear that the undulation produced by it would injure the banks of the canal. Miller and Taylor effected nothing further in steam-navigation; but Symington, many years afterwards, took out a patent under which a steam-boat called the *Charlotte Dundas* was tried for a time on the same canal, in 1803. Henry Bell, an ingenious mechanic of Glasgow, who had witnessed the experiment of 1789, pondered on what he saw, and took up the subject at a later date, after Symington had abandoned it. It was not, however, until 1811 that he placed a small steamer in operation on the Clyde; this was the *Comet*, of twenty-five tons burden and three horse-power; small as it was, it steamed down the Clyde against a head-wind at five miles an hour. Meanwhile, Robert Fulton, an American of great ingenuity and energy, taking up an unsuccessful patent of Chancellor Livingston's, adding to it various details given to him by Bell concerning Miller and Symington's twin-boat, and supplying the rest by the resources of his own mind, placed a steam-boat called the *Clermont*, of 160 tons burden, on Hudson River, in 1807; it steamed 110 miles in twenty-four hours. Space is wanting here to discuss the relative merits of Miller, Taylor, Symington, Bell, and Fulton, as inventors in steam-navigation; all we can say is, that society owes to those ingenious individuals a debt above all price.

Thenceforward the progress of steaming was steady and rapid. The first steam-boat on the Thames, the *Margery*, seventy tons burden, and fourteen horse-power, ran between London and Gravesend in 1816; from this small beginning, forty years of improvement have developed a fine system of Thames steam-navigation. The Clyde, however, has been still more associated with these improvements. After various minor trials between 1811 and 1818, Mr David Napier sent a steamer from Greenock to Belfast in the last-named year; it was the *Rob Roy*, of ninety tons and thirty horse-power, that thus had the honour of being the first vessel to steam across a sea. He next planned the *Talbot*, to run between Holyhead and Dublin; and soon afterwards he established a line of steam-ships between Glasgow and Liverpool. In America, the length and commercial importance of the rivers enabled that country to take a lead it has ever since maintained in *river*-steaming. About the year 1813, Mr Stevens made a steam-voyage from New York to the Delaware, along the Atlantic sea-board. In 1819, the *Savannah* crossed the Atlantic from New York to Liverpool; but she being chiefly propelled by her sails, this cannot be called a steam-voyage. Later stages of progress we shall notice presently in connection with the chief steam-shipping companies.

Referring to the article STEAM-ENGINE for a description of the various kinds of engines used for marine purposes, we will proceed to notice the *paddles* and *screws* whereby steam-power is rendered available.

Where paddles are employed, they consist of two wheels attached to the ends of a shaft running across the vessel, which shaft receives motion from the engines. The paddle-wheels hang over the sides of the vessel, and dip into the water. They have boards or *floats* at the circumference, parallel with the axis; and it is to the resistance offered by the water to the movement of these boards that the motion of the vessel itself is due. When each board is firmly fixed in position, it enters and leaves the water obliquely, exerting less working effect than if it entered and left the water with its plane vertical. Various modes of obtaining this verticity have been introduced, under the names of *feathering* paddles, *cycloidal* paddles, &c. A somewhat higher speed is attained in many of the American steamers by dividing each float-board into three parts longitudinally, in such way that each part may enter the water alone, thereby lessening the amount of beating or splashing.

Paddle-steamers, however, are rapidly yielding in favour to *screw*-steamers, except where high velocity is needed. The chief points of superiority are that, if sails be also used, the screw can be unshipped in weather favourable for sailing; that steam and sails can be used jointly in moderate winds; that less fuel need be taken, and less used; and that the absence of paddle-boxes is a great advantage, especially for war-steamers. Although screw-propellers had been theoretically advocated much earlier, it was not until 1836 that a method, patented by Mr J. P. Smith, came to be taken up in earnest by

engineers. His plan consisted in placing the screw or fan in a square aperture in the 'dead-wood' immediately in front of the rudder. The screw is made to rotate on a horizontal axis by a steam-engine, and drives the ship along by the resistance offered by the water to this rotation. Sometimes the screw consists of one thread, making one turn round the shaft or axis; sometimes of two or more threads, each making only a portion of a complete turn: the curvatures and adjustments being very varied, and the best form being still an unsolved problem. Screw-steaming having been found very useful as an auxiliary to sailing, engineers have adopted means of placing the screw out of the way when not wanted, since it would obstruct the ship's motion if immersed in the water without rotating. A new mode of propulsion has recently been brought forward by Mr Ruthven, in which the power of a centrifugal pump, worked at a high velocity by steam-power, is employed to force a current of water through nozzles placed at each side of the vessel: the resistance of the sea or river to this current drives on the vessel, by reaction.

Iron, as a material for ship-building, has come very extensively into use since the great employment of steam-propulsion. It is preferred to wood on account of its superior buoyancy, the facility of working it, its greater tenacity, and its greater cheapness for large vessels. One especial advantage is in the facility offered for the making of bulkheads, partitions, or transverse iron walls in a ship, whereby the interior is divided off into separate water-tight compartments. The Board of Trade returns shew how rapidly iron steamers are taking the lead of those built of timber. In the year 1855, of 233 steamers built in the United Kingdom, no less than 195 were of iron. The British-built steamers of all kinds, registered in the ports of the United Kingdom on the 1st of January 1856, were 1674, presenting an aggregate of 380,635 tons, or an average of about 230 tons. Our sailing-ships, on the same day, numbered 24,274, of 2,968,699 tons, or an average of about 122 tons.

Most of the improvements in steam-ships have been introduced under the auspices of the ocean mail companies. A company was formed at Bristol in 1836, to establish a mail-steamer from that port to New York; it was calculated that a steam-ship might make the outward voyage in twenty days, and the homeward in thirteen; instead of thirty-six and twenty-four days, as needed by the sailing-ships of that period. The *Great Western*, of 1340 tons, and two engines of 225 horse-power each, was accordingly built, under the engineering superintendence of Mr Brunel. Triumphing over predictions of failure, this steamer crossed the Atlantic in safety in 1838, under the command of Lieutenant Hosken. The success was mainly due to the power of carrying coals—namely, 600 tons—sufficient for the entire voyage of 3000 miles; of this quantity, 450 tons were consumed. The voyage was made in fifteen days, between April 8 and April 23. In the same month, the *Sirius* made a voyage from Cork to New York in nineteen days, between April 4 and April 23; but she was aided by sails; so that the problem of transatlantic steaming was really solved by the *Great Western*. Between 1838 and 1844, this fine vessel crossed the Atlantic eighty-four times, the average of the voyage being 14½ days. The same company afterwards built a much larger steamer, the *Great Britain*, which, after being stranded on the Irish coast, was purchased by a Liverpool firm, and placed on the Australian route. The *President*, another Bristol steamer of large size, was lost at sea; and the *British Queen*, a fourth, was sold to the Belgian government.

In July 1840, the Cunard mail-steamers began to run between Liverpool and Halifax; the first three employed were the *Britannia*, *Acadia*, and *Caledonia*, each about 1140 tons, with engines made by Mr Robert Napier of Glasgow; but larger vessels were built at a later date, such as the *Hibernia* and *Cambria*, of about 1420 tons each; and the *America*, *Niagara*, *Europa*, and *Canada*, of about 1830 tons each. Urged on by competition from other quarters, the Cunard Company built still more powerful and magnificent steamers. The Collins Company, of American formation, commenced ocean-steaming in 1850; their steam-ships *Atlantic*, *Pacific*, *Arctic*, and *Baltic*, were built to excel the Cunard line; while the latter, building the *Asia*, *Arabia*, *Persia*, and other noble vessels, resolved to maintain the precedence they had gained. Many of these superb steamers have cost more than £100,000 each, and exceed 3000 tons register. One of the Collins steam-ships, the *Arctic*, was unhappily wrecked near Newfoundland in 1854, with a loss of 300 passengers and crew. The grandest of these Atlantic steamers, the *Persia*, which made her first voyage in 1856, is 3600 tons register. So wonderful have been the improvements wrought by this competition, that a transatlantic voyage has become practicable in ten days. All the voyages of both companies in 1856, outward and homeward, presented an average of twelve days' duration for each.

Previous to 1836, the steam-route from England to India was very incomplete; but in that year the Peninsular and Oriental Company was established, to place the transit on a better footing, by having steamers from England to Alexandria, land-transport to Suez, and other steamers from Suez to India. Operations commenced in 1838; and during nineteen years, the ships employed have been gradually increased in size and power, and the route so extended as to include Singapore and China as well as the India ports. In the first ten years, the company built and employed twenty-six steamers, ten of iron, and sixteen of wood; the largest of these were the *Precursor*, of 1817 tons; the *Bentinck*, of 1974; and the *Hindostan*, of 2018. Since the year 1848, a fleet of magnificent large steamers has been added. One of the most celebrated was the *Himalaya*, an iron screw-steamer of 3550 tons, which began its career in 1854; it was bought by the government as a troop-ship some months afterwards, and was employed with great advantage during the Crimean war: whereupon the company built the *Pera*, launched early in 1856.

In 1842, mail-steamers were established to run from Southampton to the West India Islands; and the line has continued during fifteen years in the hands of the same company. The steamers, mostly named after rivers, have been gradually replaced by others of greater tonnage, as the trade extended. The *Thames*, *Trent*, *Medway*, *Teviot*, *Severn*, *Dee*, *Avon*, and *Clyde*, placed upon the route during the first ten years, were all between the limits of 1666 and 1886 tons; but since 1851, other steamers of much greater magnitude and splendour have been built. One of these, the *Amazon*, was burned on her first voyage out, in January 1852; and another, the *Demerara*, was stranded while being towed from the builder's yard at Bristol. The *Atrato*, an iron paddle-steamer of 3460 tons, gained great celebrity in 1855 and 1856 by making the quickest voyages ever known to and from the West Indies. One of the finest steamers of this line, the *Tyne*, was stranded on the Dorset coast in January 1857.

Steam-voyages to Australia have not, down to the beginning of 1857, been commercially successful—in part through indecision of the government, and in part through engineering causes presently to be explained. A company started vessels on this route in 1852. The first voyage was made by the *Australian*, a Clyde-built iron steamer; she stopped at four places to take in coals, and reached Melbourne, about 12,000 miles distant, in ninety-one days. The *Argo*, and other steamers belonging to the same company, afterwards ran the distance in sixty-five to seventy days. A fine screw-steamer, the *Crœsus*, of 2500 tons, started from England to Australia in 1854. In the same year, the *Golden Age*, an American steamer, crossed the Pacific from Sydney to Panama, being the first steamer that did so: she made

this voyage of 7950 miles in thirty-nine days, including six days' detention at Tahiti. In the same year, also, was effected the first circumnavigation of the globe by steam; the *Argo* having gone to Australia round the Cape of Good Hope, and returned round Cape Horn, each voyage being made in about sixty-five days. The Admiralty has entered into a contract for mail-service to Australia in 1857, by clipper-ships with auxiliary screws. The efficacy of the screw for ocean-steaming was mainly demonstrated by the General Screw Steam Company, connected chiefly with the African and Mediterranean routes.

Nothing can better shew the opinion of ship-builders and companies concerning the advantages of great length of hull in attaining speed, than the following list of six steamers, built at six different dates:

	Length.	Breadth.
1825 Enterprise (built for India), . . .	122 ft.	27 ft.
1835 Tagus (first Mediterranean steamer), .	182 〃	28 〃
1838 Great Western (first Atlantic steamer), .	236 〃	36 〃
1844 Great Britain (first ocean screw-steamer),	322 〃	51 〃
1853 Himalaya (largest screw-steamer), .	370 〃	44 〃
1856 Persia (longest paddle-steamer), .	390 〃	45 〃

The largest war-steamer now (1857) afloat, the *Duke of Wellington*, is shorter than the *Persia* by no less than 150 feet; whereas it is 9 feet broader than the broadest merchant-steamer. This illustrates the difference in qualities required for war and for mail-transit.

The Future of Ocean-steaming—the *Great Eastern*.

The *Great Eastern*, the most wonderful specimen of naval architecture yet attempted, was suggested by certain disadvantages inherent in all the steamers previously built. An adequate supply of steam has been the great desideratum; for it is owing to a deficiency in this requisite that steamers, in very long voyages, have hitherto borne all the expenses without reaping all the advantages of that mode of propulsion. A sailing-ship finds wind to fill her sails at all seasons and in all seas, with certain rare exceptions; but if a steamer has to go out of her course to procure coal for the furnaces, and if a period of twelve, or even twenty days be thus lost, the advantages of high speed become almost neutralised, and a sailing-ship of clipper build will make a long voyage almost or quite as quickly as a steamer. This has been the state of the case in respect of Australian steamers down to the present time (1857): the coal-question has been the great difficulty. When, therefore, an Eastern Steam Navigation Company was formed in 1852, the problem was discussed whether a steamer could be built large enough to carry coals for (say) 23,000 miles of steaming, to Australia and back; and whether, if so built, it could be navigated swiftly and safely over the ocean. The solution of this problem was left to Mr Brunel, who had many years before triumphantly shewn, by the planning and engineering of the *Great Western*, that a steam-voyage across the Atlantic is easily practicable. The old poetic imagery concerning waves 'mountains high' has wrought some mischief, since it has led ship-builders to cramp their own movements by fear of those waves. Prophets foretold that so long a ship as the *Great Western* would 'break her back' if perched up on a mountain-wave; not only has this been disproved, but longer ships have become more and more prevalent. It has been found that ocean-waves are much shallower and narrower than used to be supposed; and a calculation is made that a ship 600 feet long would always rest on the crests of three or four waves at least, unless in a storm of unusual severity. Mr Brunel planned that the great length of his vessel should adapt it for ordinary waves, while great strength of construction should enable it to resist exceptional dangers. The *Persia* has made fourteen and a half knots an hour; and Mr Brunel has shewn that even a small increase on this speed would shorten an Australian voyage to thirty-five days—provided there were no stoppages for coaling: indeed, he contends that sixteen knots—nearly twenty statute miles—per hour might be produced with a smaller power in proportion to tonnage than ordinary vessels have hitherto required to produce ten. Not only is the *duration* of a voyage increased, but its *cost* also, by the necessity for coaling on the way. To supply Australian steamers hitherto, coals have had to be taken from England nearly half over the globe by other ships, to form coal-depôts; insomuch that every ton, all expenses included, costs four times as much as at the English ports: this, on a consumption of 4000 or 5000 tons out and home, becomes a serious matter, and is the chief cause why Australian steaming has hitherto been unprofitable.

After mature deliberation, the company and the engineer determined to build a steamer nearly 700 feet in length, that might contain 12,000 to 14,000 tons of coal, 5000 tons of measurement goods, and 4000 passengers besides crew—a daring thought, worthy of an age of high mechanical and commercial attainments. Mr Scott Russell was selected as the builder, and a plot of ground adjacent to his works at Millwall was leased by the company as the place of building. The building-yard was prepared by piling to an immense depth, and was provided with engineering-shops, foundries, forges, rolling-mills, and all the appliances for building an iron ship. Without tracing the progress of the works year by year to 1857, it may suffice to describe briefly the ship itself, supposed to be finished.

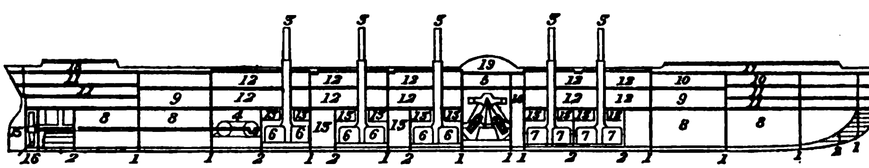
The length of the *Great Eastern** between the perpendiculars is 680 feet, and on the upper deck, 692 feet; the breadth of the hull, 83 feet; and including paddle-boxes and their fenders, 118 feet—equalling the width of Portland Place, one of the broadest streets in London, or in England; the height of the hull is 60 feet; the weight of iron in the hull is 7000 tons; the launching-weight, 10,000 tons; and the weight of the whole ship when voyaging, with every contemplated article and person on board, not less than 25,000 tons! At this full load she will draw 30 feet of water. The hull of the ship is a system of ribs or webs, 35 in number, running longitudinally from stem to stern, up to about five feet above deep-water line, and divided by vertical ribs at certain intervals, so as to present a series of oblong quadrangular openings. Into these openings are fitted two series of iron plates, three-quarters of an inch in thickness, strongly riveted to the ribs by means of angle-irons; these plates form two walls or skins to the ship, thirty-four inches asunder. Thus the double wall is a system of iron cells, presenting, like the Menai Bridge, the maximum of strength with the minimum of material. There is no external keel; the bottom is quite flat and cellular like the rest. Every one of the 10,000 or more thick iron plates used in the hull has had a particular curve given to it, to adapt it to the shape of the vessel. More than 2,000,000 rivets have been used in fastening the plates and ribs—all inserted and hammered while white hot.

The interior of the ship is thus arranged: Running crosswise are ten or twelve iron water-tight bulkheads or walls, extending the entire height to the upper deck, with no openings below the lower deck; the ship is thus cut off into ten or more compartments, generally about sixty feet long, any one of which might be filled with water up to the level of the lower deck, without flooding any of the others—a matter of great importance in the event of shipwreck. Five of the compartments near the centre of the ship form five complete hotels for passengers; each comprising upper and lower saloons, bedrooms, bar, offices, &c.; and each cut off from all the others by the iron bulkheads. It is as if five hotels, each measuring about eighty feet by sixty, and twenty-five feet high, were let down into an equal number of

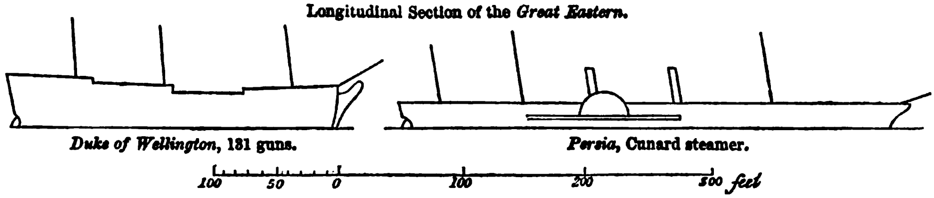
* For various drawings and details relating to the ship, we are indebted to the kindness of Mr Jacomb, assistant-engineer in its construction.

vast iron boxes. Vertical longitudinal walls separate each compartment into central saloons, and side-cabins, or bedrooms, and decks, separate the height into two series of such rooms. The arrangements are intended for 800 first-class passengers, 2000 second-class, and 1200 third-class and soldiers. The crew and engineers, 400 in number, will be accommodated near the two ends of the vessel. The upper deck is flush fore and aft, except sky-lights and ventilating openings, thus presenting a promenade nearly *an eighth of a mile* in length; it has an iron basis, double and cellular, like the hull. The arrangements are planned with an amount of room and comfort for each passenger never attempted in other ships: the upper saloons being twelve feet in height, and the lower nearly fourteen.

The means of propulsion are vast in power and unprecedented in combination, since they include the paddle, the screw, and the sail. The paddle-wheels are 56 feet in diameter, larger than the circus or arena at Astley's Amphitheatre, with float-boards about 13 feet long. They are driven by engines with four cylinders, the largest ever made on the oscillating principle; the cylinders have a diameter of 74 inches, and 14 feet stroke. These engines, standing nearly 50 feet high, were made by Messrs Scott Russell at the Millwall works. The screw-propeller, 24 feet in diameter, with four fans or vanes, and a shaft 160 feet long, and 60 tons-weight, is driven by two engines made by Messrs Watt of Soho—the largest ever made for marine purposes; they have four cylinders 84 inches in diameter, with 4 feet stroke. Each cylinder for the screw-engines was cast in a single piece, and required thirty-four tons of molten metal in the casting. The under half of the ship is divided by several iron partitions and arches, as well to strengthen the structure as to accommodate the machinery. The coals are ingeniously packed around and above the boilers, so as to be near at hand, and to shield the passengers from the heat of the boiler-rooms. There are four enormous boilers to supply steam for the paddle-engines, and six for the screw—the furnaces being so constructed as to burn either anthracite or common steam-coal. The transverse bulkheads or iron partitions, as has been already described, form impenetrable barriers between the compartments; but to facilitate the passage of workmen, pipes, &c., iron tunnels are driven through the partitions and the coal-bunkers, rendered everywhere water-tight. Sails will not be needed in the ordinary state of the weather; but to take advantage of a very brisk wind in a favourable direction, and to assist in steadying and steering, there are six masts carrying 6500 square yards of canvas. To aid the 400 sailors and engineers in working the ship, there are auxiliary steam-engines, from which power may be 'laid on' for hoisting sails, heaving anchors, pumping, &c. There will be ten anchors, 800 fathoms of chain-cable, and numerous capstans and warps. The plans include an electric telegraph to communicate orders to various parts of the ship—especially from the commander to the engineer, the look-out man, and the helmsman. Gas will be made on board, to light the various parts of the ship. In order to leave no precautions for safety unprovided, there will be boats enough



Longitudinal Section of the *Great Eastern.*



Relative lengths of the largest ships yet built, 1857.

to contain all the passengers and crew: two of them being screw-steamers 90 feet long, hung on davits abaft the paddle-boxes.

The great length of this vessel has rendered necessary the adoption of a new plan for launching. In ordinary circumstances, a ship is built on a sloping ground or slip, with a descent of about one foot in fourteen towards the water-side; but in this instance the vessel is built on a level, broadside towards the river. For launching, two timber platforms of immense strength are formed, from the ship's position to low-water mark; each platform eighty feet in width, smooth at the top, and having a slope towards the water of one in twelve, is supported by a vast substructure of piles driven into the ground. Two cradles of massive timber are built temporarily under the hull, one between the midship and the head, the other between the midship and the stern; and when all subsidiary arrangements are ready, these two cradles slide down the two platforms, carrying the monster-ship —*twenty million pounds-weight*—with them. This is done at low-water, and the rising tide floats the vast fabric.

The following references apply to the wood-engravings. In the longitudinal section of the *Great Eastern:* 1, Main transverse bulkheads; 2, Partial bulkheads beneath lower deck; 3, Funnels from the five pairs of boilers; 4, Screw-engines; 5, Paddle-engines; 6, Screw-engine boilers; 7, Paddle-engine boilers; 8, Cargo space; 9, Cargo

and horse space; 10, Officers' and crew's berths; 11, Capstans, chains, anchors, &c.; 12, Passengers' saloons; 13,

Coal-bunkers; 14, Auxiliary engine-room; 15, Rudder; 16, Screw-propeller; 17, Forecastle; 18, Space for live-stock; 19, Paddle-box. The relative lengths are shewn of the *Duke of Wellington*, the longest war-ship, and the *Persia*, the longest ocean-steamer afloat previous to the launching of the *Great Eastern*, with which they are both placed in comparison by the adoption of the same scale. In the midship section: 1, Upper saloon; 2, Cabins; 3, Cabins, baths, &c.; 4, Lower saloon; 5, Tunnels; 6, Coals; 7, Boilers. This section also shews the cellular structure of the double skin round the lower part of the hull, and of the upper deck.

NAVIGATION.

Navigation is the art of conducting vessels at sea in the direction in which they are designed to proceed; the term is derived from the Latin word *navis*, a ship, and *ago*, to manage or govern. From *navis* also is derived the term *navy*, which signifies a collection of ships. The terms *marine*, *maritime*, and *mariner*, are likewise from a Latin root—namely, *mare*, the sea.

Laying aside the consideration of steam as a moving-power, vessels may be said to advance in their course by means of tides, currents, and winds; the winds are in most instances the principal agent, and the art of the mariner consists in rendering almost every breath of wind which blows subservient to the purpose of the intended voyage. The winds most favourable for impelling the vessel are those which blow on the *quarter*, or slantingly on the ship's course. The reason for this is very obvious: when the wind blows directly astern, it can affect only one or two sails with commensurate force; but when it comes obliquely, every sail may be trimmed to meet it, and receive a share of the impulsive power. The variety in the rigging of vessels causes much difference in sailing powers: some will sail close to the wind, as it is called, or with a very small angle to the direction of the breeze, while others require winds much more fair. When the wind becomes too powerful, certain sails are taken in, and others are *reefed*, a portion being bound to their respective yards, so as to reduce the surface of canvas. Reefing and bracing the yards are among the nicest points of seamanship.

Ships are navigated, as nearly as possible, by the path which is the shortest distance between the port whence they depart and that for which they are destined; but from contrary winds and intervening land, it is generally necessary to sail in a track of a zigzag form. When a vessel is obliged to sail to the right or left of the direction of the intended port, it is said to *tack;* when the ship is tacking towards the left, and the wind consequently on the right, it is said to be on the *starboard* tack; and when it is tacking towards the right, it is said to be on the *larboard* tack. A ship does not sail exactly in the direction of her keel, but deviates towards the side that is opposite to the wind; and the angle contained between the apparent and real direction is called *leeway*.

The tacking or changing of directions, in order to present the sails at a proper angle to the wind, is a process requiring considerable seamanship. The ship being already close to the wind, the helm is gradually eased *down*, so that the rudder may not exert its full force until she begins to turn, nor act suddenly to check the headway, so essential to the success of the evolution; at the same time the head-sheets are flown, so as to cause the sails before the centre of rotation to shake, and lose their power of balancing the after ones. As the ship approaches the wind, the spanker is drawn gradually from the lee-side towards the centre, that it may keep full, and by its action so near the stern, continue promoting the rotation. As soon as the sails reach the direction of the wind, and cease to draw, the corners of the courses are drawn up, and the tacks and sheets overhauled, ready to swing the yards. After a while, the sails catch aback, and the foresails, soon making the after ones, act with a powerful leverage in turning the bow. At length, having come head to wind, without loss of headway, and the evolution being certain, the after-yards are swung round, ready to receive the wind on the opposite side; which operation is then more easily performed, from the sails being becalmed by the fore ones. Lastly, when the after-sails are filled by the wind, the head-yards are also braced round to receive its impulse, and the ship at once recovers headway, and proceeds on her new tack.

Thus easily is a ship manœuvred in fine weather. Not unfrequently, however, a gale comes to disturb the peaceful course of the mariner, and call forth all his exertions. Let us suppose that, whilst our ship is contending against the head-wind, the misfortune is augmented by its gradual increase. Shortening sail becomes necessary, and is determined by two leading considerations—the stability of the ship and the strength of her masts: it is to diminish the careening of the one, and avoid endangering the other, that the surface spread to the wind is reduced. In shortening sail, we always begin with the highest and lightest sails, descending gradually, and keeping pace, in an inverse ratio, with the increase of wind. The sails do not, however, come in uniformly in the direction of the length; but the after-sails most rapidly; because, as the wind increases, the energy which it exerts in a forward direction upon the masts, tends, with a powerful lever, to depress the bow and raise the stern. Hence the latter drifts more easily to leeward, thereby bringing the bow towards the wind; this effort is also promoted by the action of the sails passing further to leeward, and by the ship ceasing to sail on an even keel. From all these reasons, the more the wind increases, the more she tends to come to; so, to avoid a constant recurrence to the action of the rudder, it becomes necessary to shorten sail faster aft than forward, taking in the mizzen-top-gallant-sail, and even the spanker, before the fore and maintop-gallant-sails: for the same reason, when it becomes necessary to reef, it is not unusual to begin with the mizzen-top-sail. In the case of a heavy gale, it is sometimes necessary to reef or take in the whole from stem to stern; the helm being at the same time kept constantly hard down, the vessel is said to *lie to*.

The Compass.

The most important instrument for the guidance of the mariner is the compass. There are different kinds of compasses, to suit peculiar purposes; but that which is commonly in use on shipboard is of the following construction:—The most essential part is a magnetised bar of steel, called the needle, which is supported horizontally on a central pivot, round which it is free to move and to point in any direction. The pivot of the needle rises from a circular *card*, resembling the dial-plate of a time-piece, and round the circumference of which are marked thirty-two points. The figure on next page represents the card of a compass. North, South, East, and West are the main or cardinal points, and are indicated by their initial letters respectively, while the subordinate points are also marked by letters—as, N*b*E, for north-by-east; NNE, north-north-east; and so on. To recite the various points is called 'boxing the compass.' The north is usually indicated by an ornamented figure, or arrow-head, as in the annexed sketch.

The card and needle are fixed in a round box, enclosed by a sheet of glass, to secure it both from the agitation of the atmosphere, as well as to exclude dust, moisture, and other things which might interfere with the correctness of the indications. The whole is enclosed in another box, suspended by two concentric brass circles or *gimbals*, as they are technically called, and in such a manner that the compass hangs as it were on points like a swivel, by which, during the lurching, or heaving up and down,

or motion from side to side of the ship, the needle and its card remain in a horizontal position, and under all

circumstances indicate the various points correctly. The compass, thus incased, is placed upon deck in a covered stand, called the *binnacle*, in front of the man at the helm, so that the direction in which the needle points can be constantly seen in guiding the vessel. The point of the needle—which, for distinction, is some way ornamented—is understood to point towards the north, but it is only at very few places on the earth's surface that it points due north. It has almost everywhere a *variation* or *declination*, either to the east or to the west of north; and this, as well as other variations to which it is subject in certain latitudes, must be thoroughly understood by the navigator. (See ELECTRICITY—MAGNETISM).

The needle being liable to be affected by the proximity of iron, no piece of that metal is used in the construction of the binnacle, or is allowed to be near it. In the case of iron ships, or ships having much iron on board, means are adopted to counteract the tendency which the needle has to point in a wrong direction; but the subject is attended with difficulty, and is still undergoing investigation. The most effectual way, it seems, yet found of guarding the compass from the deranging effects of the metal in the ship, is to place it high above the deck.

The Log—Sextant.

Provided with a compass, the next object of importance is the *log*, an instrument for measuring the rate at which the vessel proceeds through the water in a given space of time. The log is a very simple contrivance. It consists of a long cord, having a piece of wood attached to one end, and called the *chip*. This is of a quadrantal form, and being slung at the corners with line, and loaded at the circumference, when thrown overboard it remains erect and stationary, and drags the line off as fast as the ship passes through the water. The line is divided into knots and half-knots, representing miles and half-miles, or minutes of a degree, to which they bear the same proportion as the log-glass does to an hour. Thus, the log-glass being filled with sand to run through in 30″, the length of a knot must be 51 feet, the first being the same proportion of an hour that the last is of a mile. As, however, the log is found to come home a little in the effort to draw the line out, it is customary to mark the knot a foot or two less than the true length. The mode of heaving the log to measure a ship's rate is as follows: The log-reel, upon which the line is wound, being held by one of the sailors, the officer places himself on the rail to leeward, and a third person holding the glass, he proceeds to prepare the chip, so that the peg of one of the lines holding the chip in a perpendicular direction will draw out, by the force of the water, when the reel is stopped, and allow it to haul in easily. Then having gathered a sufficient quantity of line into his hand, he throws it far to leeward, that it may not be affected by the eddies which follow in the wake. The stray line, which allows the chip to get astern, now runs off, and the instant that the white rag, which marks its termination, passes through the hand of the officer, he cries 'Turn!' and continues to veer out line until the glass runs out, and the person holding it cries 'Stop!' Then the line is grasped, and the number of knots that have passed off mark the speed of the ship. When this exceeds five miles, it is usual to use a glass of 15″ instead of 30″, counting the knots double. The rate of sailing per hour multiplied by the hours sailed, thus gives the mariner the measure of his run.

In addition to these essential instruments for directing the course and ascertaining the distance, the navigator must be provided with *octants* of double reflection, to measure the altitude of the heavenly bodies, and a circle, or *sextant*, more nicely graduated, to measure distances between the moon and stars. He should also have with him a book containing the logarithms of numbers, sines, tangents, and secants, to facilitate trigonometrical calculations; tables for correcting altitudes for dip, parallax, and refraction; also lists of latitudes and longitudes for every part of the world; and of time of high-water at every port, at the period of full and change of the moon, from which at all times to be able to find the tide; and a variety of tables to facilitate the various problems of navigation. He should also have with him the *Nautical Almanac*, containing the places and declinations of the fixed stars and planets, and especially the distances of the moon from the sun and other stars, and all that relates to that body, with a view to calculate the longitude by observation. Finally, he must be provided with the general and local charts applicable to his contemplated voyage.

Thus furnished, the mariner may set sail with confidence; many do so with no other aids than their compass, log, quadrant, a single chart, and book of navigation, and arrive in safety. But it is less our business to shew with how little care a ship may be navigated, than to shew how she may be carried from port to port with the greatest possible certainty. Having taken leave of the port, and when the last land is about to disappear from view, either from the growing distance or the intervention of night, the mariner selects some conspicuous headland, of which the latitude and longitude are noted in his tables, and placing a compass in some elevated position, remote from any iron object to disturb its polarity, proceeds to determine its bearing, and estimate his distance from it, either by the progress made from it, or by the ready estimate of a practised eye. Or taking the simultaneous bearings of two distinct points of coast, he has still surer data for deducing his position. This is called *taking the departure*, and is carefully noted on the log-slate, with the time of making the observation. Thenceforth the log is thrown every hour, and the course and distance are entered upon the slate, to be copied into the log-book at the end of the day.

Working a Reckoning.

At the first noon succeeding the time of taking his departure, the mariner works up his reckoning. Noon is an epoch fixed by nature, being determined by the passage of the sun over the meridian, and is therefore well chosen as the beginning of the day. The log-slate being marked, he copies the courses and distances, if from head-winds or other causes, they have been various; the departure from the land is also converted into a course; as is also the current, if there be any known one. He next proceeds to find the difference of latitude and departure from the meridian corresponding to each course, either by geometrical calculation, or more expeditiously, by reference to tables; then he adds the several differences of latitude and departure, and if they be of different names, as some north and some south, some east and others west, deducts the less from the greater. With the remaining difference of latitude and departure, he not only finds the course and distance made good, but

also the latitude and longitude in which he is; the difference of latitude being applied to the latitude left, by adding or subtracting, in sailing from or towards the equator, at once gives the latitude of the ship. But before the departure can be thus applied to find the longitude, it is necessary to reduce it for the converging of the meridians towards the poles; for though all degrees of longitude are divided, like those of latitude, into sixty minutes or miles, yet they decrease in length from being equal to a degree of latitude at the equator, until they become nothing at the poles. There are many ways, more or less accurate, of deducing the difference of longitude from the departure, the latitude being known; they are founded upon this principle: the circumference of the earth at the equator is to its circumference at any given parallel of latitude as the departure is to the difference of longitude. The most easy and correct way of obtaining the difference of longitude on an oblique course, is by the aid of a table of meridional parts; for having taken out the meridional difference of latitude, the mariner has this simple proportion—the proper difference of latitude is to the meridional difference of latitude as the departure to the difference of longitude. The difference of longitude thus obtained is applied to the longitude left, adding or subtracting in sailing to or from the first meridian, and the result will be the ship's longitude; which, with the latitude previously ascertained, determines her position on the chart. The method of navigating thus described is called *dead reckoning.* It is far from infallible, and leaves much to desire. It will indeed do pretty well in short runs; but as errors daily creep in from any causes escaping calculation, such as bad steerage, leeway, heave of the sea, unknown currents; and as these accumulate, and become considerable at the end of a long voyage, it becomes necessary for the mariner, removed from all reference to terrestrial objects, to resort to the immovable guides in the heavens. All the heavenly bodies are, by the revolution of the earth, daily brought to the meridian, at which time, if their altitude is measured, their declination or distance from the equinox being known, the latitude is readily deduced; it may also be deduced from single or double altitudes of bodies not in the meridian, the times being accurately known. But the meridian altitude of the sun is what furnishes at once the easiest and most correct method of finding the latitude.

Taking an Observation.

Furnished with a sextant, circle, or octant of reflection, the observer goes upon deck, and having examined the adjustment of his instrument, proceeds to bring down the image of the sun reflected by its mirror, until the lower limb just sweeps the horizon. He continues to follow and measure its ascent, until it ceases to rise; the moment that it begins to fall, and the lower limb dips in the horizon, the sun has passed the meridian. The altitude marked by the index being read off, it is next corrected. And first, the observer adds the semi-diameter, in order to make the altitude apply to the centre of the object; next he subtracts the dip, to meet the error caused by the extension of the horizon, in consequence of the rotundity of the earth, and the elevation of his eye above its surface; also the refraction of the atmosphere, by which the object, when not vertical, is made to appear higher than its true place; lastly, he adds the parallax—a small correction inconsiderable from the sun's distance—in order to reduce the calculation for the centre of the earth; from which point all calculations are made, and which is ever supposed to be the station of an observer.

Having made all these corrections, which many mariners despatch summarily, by an addition of twelve minutes, he has the true meridian altitude of the sun. Taking this from a quadrant, or ninety degrees, gives its zenith distance, or distance from that point in the heavens which is immediately over the observer, and would be met by a straight line passing from the centre of the earth through his position. Now, if the sun were for ever on the equinoctial, the zenith distance would always be the latitude; for whilst the zenith is the observer's position, referred to the heavens, the equator is there, in like manner, represented by the equinoctial; and we have already seen that latitude is the distance from the equator. But as the sun is only twice a year upon the equinoctial, and as his distance from it at times increases to more than twenty degrees, it becomes necessary to take this distance—called his *declination*—into the estimate. The sun's declination is given in the Almanac for the noon of each day; by correcting it for the time anticipated or elapsed, according as the sun comes first to him or to the first meridian, by his position east or west of east of it, the observer obtains the declination for noon at his own position. This declination applied to the zenith distance, by adding when the sun is on the same side of the equator, by subtracting when on the opposite side, gives the true latitude.

A daily and accurate knowledge of his latitude is, then, to the mariner of modern times, a desideratum of comparatively easy attainment. By its aid, nothing is easier than to sail clear of any rock or shoal that crosses his track, either by a watchful look-out at the moment of passing its latitude, or else by avoiding its parallel entirely, until it be surely passed. Moreover, this is his best and surest guide in aiming at his destined port; for he has but to attain the exact latitude it lies in, and then sail directly upon it, east or west, to be sure of success. And here nature is again his friend: by a singular coincidence, discoverable in glancing at the map of the world, most coasts and continents lie in a northern and southern direction. Hence the value attached by seamen to an accurate knowledge of the latitude; and hence the familiar saying of 'Latitude, lead, and look-out.'

To find the Longitude.

Various ways have been devised to find the longitude, in all of which the great element is time. The earth performs her diurnal revolution in twenty-four hours, or, in other words, each part of the circumference of the globe, which is divided into 360 degrees, is brought under the sun once a day. Hence each part of the circumference—reckoning from east to west—has its own peculiar time of day. When it is noon at one place, it is one o'clock afternoon at another place, two at another, and so on; the time differs all round the globe. Dividing the 360 degrees by 24, we find that 15 is the result; for every 15 degrees, therefore, along the circumference going westward, there is an hour of difference, in advance; and going eastward, an hour behind. If it be noon at Greenwich, it will be one o'clock at a point 15 degrees east from it—that is, the sun has passed over it an hour ago—and eleven o'clock forenoon at a point 15 degrees west from it—that is, the sun will be an hour in getting up to it. Dividing the 60 minutes of an hour by 15, the result is 4; the earth, therefore, moves under the sun at the rate of a degree, or sixty geographical miles, in four minutes, or fifteen miles in the minute, or one mile in the four seconds, or a quarter of a mile in the second. Here, then, the element of time is brought at once, and in the most satisfactory manner, to bear upon the distance of any given place, east or west from any other given place. The measuring of such a distance is called finding the longitude.

Different places on the globe have been established as starting-points in making these measurements. The French reckon from Paris, and the English from Greenwich, near London, where an astronomical observatory has been long established, and supported at the public expense. In all English works of geography, the longitude is reckoned from Greenwich, although not expressly mentioned. Navigators determine their longitude by watches or chronometers, whose movements are as exact as can possibly be obtained from mechanism. (See

HOROLOGY.) In setting out on a voyage, the chronometer is set to Greenwich time, and kept going at that time. At the hour of noon of each day, as determined by an observation with the sextant, the difference is estimated between that hour and the hour indicated by the chronometer, and that difference is the longitude east or west of Greenwich, as the case may be. Some mariners, for security, take several chronometers to sea with them, as one only is by no means a safe guide. In general, however, the masters of coasting-traders, or those who pursue short voyages by regular lines of route, depend on books containing lists of longitudes as well as of latitudes.

Marine Barometers—Log-book.

The last great requisite in navigation is a good barometer, to indicate the approach of foul weather. The most delicate instrument of this kind is the sympiesometer of Adie, by which the earliest and most certain indications are presented of coming storms. In treating of the nature and value of instruments of this kind, Dr Arnott makes the following observations: 'The watchful captain of the present day, trusting to this extraordinary monitor, is frequently enabled to take in sail, and to make ready for the storm, when in former times the dreadful visitation would have fallen upon him unprepared. The marine barometer has not been in general use for many years, and the author was one of a numerous crew who probably owed their preservation to its almost miraculous warning. It was in a southern latitude. The sun had just set with placid appearance, closing a beautiful afternoon; and the usual mirth of the evening-watch was proceeding, when the captain's order came to prepare with all haste for a storm. The barometer had begun to fall with appalling rapidity. As yet, the oldest sailors had not perceived even a threatening in the sky, and were surprised at the extent and hurry of the preparations; but the required measures were not completed, when a more awful hurricane burst upon them than the most experienced had ever braved. Nothing could withstand it; the sails, already furled and closely bound to the yards, were riven away in tatters; even the bare yards and masts were in great part disabled; and at one time the whole rigging had nearly fallen by the board. Such, for a few hours, was the mingled roar of the hurricane above, of the waves around, and of the incessant peals of thunder, that no human voice could be heard, and amidst the general consternation even the trumpet sounded in vain. In that awful night, but for the little tube of mercury which had given the warning, neither the strength of the noble ship nor the skill of the commander could have saved one man to tell the tale.'

A journal of events and observations on board ship is usually kept in what is called the log-board, and transferred thence into the log-book. The log-board consists of two boards shutting together like a book, and divided into several columns, containing the hours of the day and night, the direction of the winds, and the course of the ship, with all the material occurrences that happen during the twenty-four hours, or from noon to noon, together with the latitude of observation. From this table, which is written in chalk, and daily effaced, the officers work the ship's way, and compile their journals. From it, also, entries are carried to the log-book in an expanded form, with any observations and additional particulars supposed to be necessary. The log-book is thus the journal of the ship, and is preserved with great care for exhibition, if required, at the termination of the voyage.

LIGHT-HOUSES—BEACONS.

Beacons, warning-bells, light-houses, and the like, are among the most indispensable adjuncts of maritime conveyance; without them, indeed, it would be utterly impossible to conduct it with anything like regularity or safety. The most ancient structure of this description which we read of was the Tower of Pharos—regarded by our ancestors as one of the seven wonders. It was commenced by Ptolemy the Elder, and finished some years after by himself and his son Ptolemy Philadelphus, in the year of the world 3670, on the island of Pharos, in the Bay of Alexandria. 'It was built,' says an ancient authority, 'on the east end of this island, upon a rock of white marble, of a large square structure, on the top of which fires were kept constantly burning for the direction of vessels. It was a most magnificent tower, 450 feet high, consisting of several stories and galleries, with a lantern at top, which could be seen many leagues at sea.' This wonderful work has been demolished for ages; as also the Colossus of Rhodes, another ancient erection of a similar nature. The Light-tower of Cordouan, in France, situated upon a low rock about three miles from land, at the mouth of the Garonne, was for a long time regarded as one of the chief wonders of modern Europe. It was founded in 1584, and completed in 1610. Its lower part consists of a solid platform of masonry, 135 feet in diameter; above which, in succession, are a number of apartments, all narrowing in circumference till the upper story is reached—being in all 145 feet high.

In our own day, the most celebrated light-house is that built on the Eddystone rocks—a low reef situated south-south-west from the middle of Plymouth Sound, nearly fourteen miles distant from that port, and about ten from the promontory of Ramhead. The reef, which stretches across the Channel for upwards of 200 yards, slopes gradually towards the south to the distance of a mile, so that the swell sweeps up, as it were, an incline, till within a few fathoms of the exposed rock, where, striking against a sudden ledge, it breaks and dashes upwards to a height of forty or fifty feet. On this dangerous reef, the necessity of a light-house was early felt; and accordingly, in 1696, a gentleman of the name of Winstanley was furnished with the necessary powers to carry such a design into execution. He entered upon his task in 1696, and completed it in four years. So certain was Winstanley of the stability of his wooden structure, that he declared it to be his wish to be in it 'during the greatest storm that ever blew under the face of heaven;' a wish that was but too soon and fatally gratified, for in November 1703, while there with some workmen and the light-keepers, a storm of unparalleled violence arose, and in one night the whole fabric was swept away. In 1709, another light-house was built of wood by a Mr Rudyerd; and this structure, after braving the elements for forty-six years, was burned down in 1755. On the destruction of this light-house, Mr Smeaton, the celebrated engineer, was next applied to, who at once fixed upon the more durable material, stone, and chose for his model the natural figure of the trunk or bole of a large spreading oak. With these views as to the proper form of the superstructure, Mr Smeaton began the work on the 2d of April 1757, and finished it on the 4th of August 1759. The rock, which slopes towards the south-west, is cut into horizontal steps, into which are dovetailed and united, by a strong cement, Portland stone and granite. The whole, to the height of thirty-five feet from the foundation, is a solid of stones, ingrafted into each other, and united by every means of additional strength. The building has four rooms, one over the other, and at the top, a gallery and lantern. It is nearly eighty feet high; and since its completion, has been assaulted by the fury of the elements without suffering any appreciable injury.

Equally remarkable with the light-house of the Eddystone is that of the Bell-rock—a sunken reef, lying at the distance of eleven miles from the promontory called the Red Head, in Forfarshire, and on the highway to the Firths of Forth and Tay, two of the most frequented estuaries in the kingdom. The ledge is said

to be about 850 yards in length, and 110 in breadth; at low-water, some of its summits appear from four to

eight feet above the level of the sea; but at high-water, they are always covered to the depth of ten or twelve feet. Tradition says that the abbots of the monastery of Aberbrothock succeeded in fixing a bell, which was rung by the swell of the sea, so as to warn the mariner of his situation; but that this benevolent erection was destroyed by a Dutch pirate, who, to complete the story, was afterwards lost upon the rock with his vessel and crew. However this may have been, it was not till the beginning of the present century that a solid substantial light-house, after the model of the Eddystone, was determined upon and erected. This work was intrusted to Mr Stevenson, the Scottish engineer; was begun in 1808, and completed in 1810. Being lower in the water than any rock on which a similar building has been raised, the difficulties of the architect were greatly increased; but by preparing all the stones on shore, and conveying them in lighters to the reef, where a tender and other accommodation were provided for the workmen, his success was complete, and the revolving ruddy light of the Bell-rock now ranks among the chief achievements of British engineering. 'The light-house'—we quote the *Edinburgh Encyclopædia*—'is a circular building, measuring forty-two feet in diameter at the base, and thirteen feet in diameter at the top. The masonry is 100 feet in height, and, including the light-room, it is 115 feet. The ascent from the rock to the top of the solid, or lowest thirty feet, is by means of a kind of trap-ladder; the ascent from the level of the entrance-door is by means of a circular stair to the first apartment, containing the water, fuel, &c.; and from thence to the several apartments the communication is by wooden steps. The windows have all double sash-frames, glazed with plate-glass, besides a storm-shutter of timber for the defence of the glass against the sprays of the sea; for although the light-room is about eighty-eight feet above the medium level of the tide, and is defended by a projecting cornice or balcony, with a cast-iron rail, formed like the meshes in net-work, yet the sprays of the sea occasionally lash or fall upon the glass of the light-room, so that it becomes necessary in gales of wind to shut the whole of the dead-lights to the windward.'

Not less bold and hazardous, in point of erection, is the recent structure on the Skerryvore—a cluster of rocks just appearing above high-water in the Atlantic, between the north of Ireland and the Hebrides, from the nearest point of which it is twelve miles distant. This light-house, commenced in 1835, and finished in 1844, by Mr Alan Stevenson, son of Mr Stevenson above mentioned, consists of a tower 138 feet high, curving inwards from a basis of forty-two feet, and contains nine apartments over each other, for the accommodation of the establishment by which the light is to be maintained. The lantern consists of an apparatus of eight annular lenses revolving round a lamp of four concentric wicks, and producing a bright blaze every minute, visible to the distance of eighteen miles. The cost of the entire structure amounted, we understand, to £89,000. We particularise this and the preceding cases as illustrations of the magnitude of some of our light-houses, and of the hazard and expense encountered in their erection—difficulties which could be surmounted only at a period of great material wealth and scientific skill, and when the importance of maritime conveyance is so vast as to compel such protection.

A number of improvements have recently been made and promulgated in the construction of light-houses, chiefly with a view to the saving of time and expense in their erection. The first deserving of notice is the iron light-house of Captain Brown. This structure is composed solely of rings of cast iron, joined or cased one upon another till the requisite height be attained. The advantages of this plan are, cheapness, facility of erection, strength, and durability. Metal light-houses—that is, composed either of cast iron, wrought iron, or gun-metal—have been strenuously advocated by Mr Gordon, who, from pretty obvious data, maintains that the Skerryvore, for example, could have been erected on this principle, with equal efficiency, at little more than one-third of its actual cost. The 'screw-pile' of Mr Mitchell is another invention likely to come into use in the erection of light-houses on shoals and sand-banks. As the name implies, the basis consists of a framework of piles screwed, instead of driven home, and on this an open fabric is erected for the support of the lighting apparatus—the open structure offering no resistance to the waves. Another set of inventors have directed their attention to the improvement of the lighting apparatus—its lamps, lenses, and reflectors. As this department involves mathematical and optical principles of high consideration, we shall merely remark, that at present the lights on our coasts generally consist of Argand burners, placed in the foci of parabolic reflectors made of silver strengthened with copper. The reflectors are arranged, and the lights exhibited, in such a manner that those on the same line of coast should have some essential distinction; thus, some of them are revolving or intermittent, many are fixed, others are placed one above another, some flash every five seconds, and not a few alternately red and white. These movements are in general effected by clock-work of a very ingenious description.

The light-houses on and about the British coasts are upwards of 200 in number, and are classed as 'harbour lights' and 'general lights.' Almost all of them are now vested in public boards, as are also the marine beacons and buoys of the kingdom. The chief board of supervision and control is the Trinity House, Deptford, incorporated so early as 1515 by Henry VIII. In Scotland, the lights are under the immediate management of the 'Commissioners for Northern Lights;' those of Ireland are under a similar trust; but both Scotch and Irish are vested in the Trinity corporation. For the erection and maintenance of lights, beacons, and buoys, a rate is levied on all vessels passing them within certain limits.*

Beacons are generally placed on sand-banks, rocks, and shoals, and are either floating or stationary. When floating, they are termed buoys (already noticed); when fixed, they are either of solid masonry, or of an open framework of wood or iron. Of late, their number has

* By an act passed in 1853, the whole affairs of the trusts are placed under the control of the Board of Trade, and brought under the review of parliament.

been much increased along the British coasts; many of them being composed of cast-iron pillars, screwed and riveted together into a substantial framework, which stands thirty or forty feet above water-level, and which no storm can possibly destroy. The most remarkable of our beacons are those erected by the Trinity House—under the superintendence of Captain Bullock—on the fatal and shifting sands of Goodwin. From the number of shipwrecks constantly occurring on these shoals, these beacons are intended to serve also as a place of refuge for shipwrecked sailors. The first and largest consists of a strong framework, sunk to a considerable depth in the sands, from which rises a vertical column; and on this, at a height of eighteen feet above high-water, is placed an octagonal platform, capable of holding forty persons. The platform always contains a barrel of water, a flag ready to be hoisted, and is inscribed in eight different languages with the words 'Hoist the flag.' The second, which was erected in 1847, is of a different construction: the centre column is a tube of cast iron two feet six inches in diameter, put together in ten and twenty feet lengths; it is inserted thirty-two feet into the sand by means of Dr Potts's newly invented process of atmospheric pressure; the four surrounding tubes are of fifteen inches diameter; the whole is bolted together, and surmounted by a cage of seven feet diameter, the top of which is fifty-six feet above sand-level.*

The great defect of beacons is, that they are not visible in dark nights, when most required for the safety of the mariner. Mr Thomas Stevenson has introduced, with great success, a mode of illuminating beacons erected on rocks or shoals situated in narrow entrances to roadsteads or harbours, where it is of the utmost consequence that the exact position of these impediments should be distinguished, but upon which it is not expedient or possible to erect a light-house. This is managed by what he terms an *apparent light*, which is produced by placing a bright reflecting apparatus on the top of the beacons, to which is transmitted, from a lamp placed in the light-house on shore, a beam of light, which is dispersed by the apparatus in the required direction, producing all the useful results of a light-house; in short, it shines by *borrowed light*.

Shipwrecks—Life-preservers.

Notwithstanding every precaution of light-house and beacon, shipwrecks are continually occurring at different parts of our coasts, and to save the lives of the seamen in such cases—without reference to the fate of the vessel—has ever been a subject of earnest consideration with the humane and ingenious. During last century, several *life-boats* were invented; among others, one by Mr Lukin in 1785. But an accident which occurred on the Herd Sands of South Shields in September 1789, led to material improvements in the art of constructing these vessels. The *Adventure*, a merchant-ship of considerable bulk, was wrecked within 300 yards of the shore, in presence of an immense number of spectators; and almost every man of the unhappy crew perished, without the possibility of receiving assistance from the shore. The consequence was, that the people of South Shields met soon afterwards, and offered a reward to any one who should invent a boat capable of being launched from the shore to the aid of ships in distress. Mr Greathead gained the premium; and in 1790, a life-boat, constructed upon the plan proposed by him, was effectually used in saving the crew of a vessel stranded under circumstances similar to those of the *Adventure*. Several other trials of the life-boat proved its utility so fully, that in 1802 the Society of Arts presented the inventor with their gold medal and 50 guineas; and parliament also decreed to Mr Greathead a reward of £1200.

* Since the above was written, storms and shipwrecks, early in 1857, have destroyed the Goodwin beacons.

The Trinity House followed the example; and the Committee of Lloyd's devoted £2000 to the purpose of building boats on the same principle.

Mr Greathead's boat was well adapted for the service of the coast on which it was introduced, and is still, with some important modifications, used there; but as it was evidently incapable of service on coasts of a different nature, other forms have been introduced to meet the various exigencies of our coast-shipwrecks. The life-boat service is now divided into two branches: 'ships' life-boats'—to provide a communication from the wrecked ship itself and the shore—and what may be called 'shore life-boats,' to communicate from the shore to the ship. The latter department, which we shall consider first, received a great impulse from the prize of 100 guineas, which the Duke of Northumberland offered, in 1851, for the best model of a life-boat. To compete for this, 280 models and plans were sent to the surveyor's department of the Admiralty, to be reported upon. Captain Washington and a board of examiners went into the whole matter most thoroughly, and issued a report, in which they named fifteen points which they considered essential to be attended to in the construction of a life-boat. The prize was given to Mr Beeching of Great Yarmouth. The principal feature of this boat was the fitting of a water-ballast tank, which for a twenty-eight feet boat would contain a ton of water, and which extended three-fifths of the breadth midships, and three-sevenths of the length; the spaces left at the sides and ends being filled with air-bladders. This prize-boat has been supplied to several stations, but its success has not been so marked as was anticipated. The 'Northumberland Committee' appointed Mr James Peake, naval architect at Woolwich Dockyard, to prepare drawings of a life-boat in which all the best features of the models were combined. The same gentleman has succeeded in introducing since then a life-boat, which, by eminent authorities, is said to be very efficient as a coast life-boat. This boat is four times as long as she is broad, with a flat floor and straight sides, with considerable curvature in the direction of its length. A water-tight platform or deck is provided; the bilge-spaces are filled with blocks of light pine, instead of cork or air boxes. In the midship part of the platform, a covered well is made for holding cable, anchor, and stores. Air-boxes are provided at the sides under the thwarts, and air-compartments in the bow and stern, as high as the gunwale; these give the self-righting power to the boat, which is also aided by a thick iron false keel, bolted to the keel bottom and kelson. The boat frees itself of water by tubes passing through the bottom, and provided with self-acting relieving-valves at the height of the platform. The boat steers with oars, and is fitted to carry a small lug-sail, and is amply provided with life-buoys and every requisite for coast-service.

A form of life-boat known as the 'tubular' has been introduced by Mr Richardson; it has been severely tested, and is pronounced a thoroughly efficient boat, by first authority. It is formed of two tubes of tinned iron, forty feet long, two and a half in diameter, and tapering at either end. An iron frame unites the whole into one mass. The tubes are divided into water-tight compartments filled with air-proof bags. A life-boat on the raft-principle was introduced in 1855 by Mr Severn of the Royal Mint, Australia. The principle consists in dividing a whale-boat longitudinally, giving flat sides to each half, and keeping the two separate some eight or ten feet by strong diagonal bracing. The rowers sit above air-cases and water-ballast tanks, which are placed at the sides.

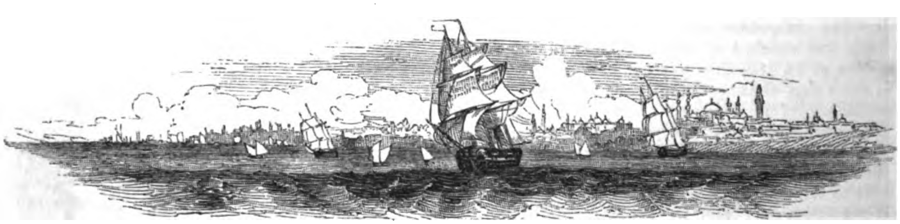
Notwithstanding all the improvements, life-boats are still not proof against heavy storms. In January 1857, the life-boatmen of Rhyl, in Wales, bravely put off to aid a distressed ship; but their boat, although of the most approved construction, was overturned, and all hands lost.

We have now to direct brief attention to the department of ships' life-boats. This is scarcely less important than that of coast-boats. George Palmer, Esq., late M.P. for Essex, was the first to introduce a boat for this purpose. It was built as a whale-boat, sharp at both ends; buoyancy being obtained by air-casks and cases in the wings, bow, and stern, under the thwarts. Mr A. Henderson, a civil engineer, who has devoted much of his attention to life-boats, has introduced a method of applying the life-boat principle to ship-boats, as ordinarily in use. The buoyancy is obtained by 'side-compartments between a rising plank, fore and aft under the thwarts, ... and a fore and aft platform over the bulkhead at the bilge; the bow and stern partitions to be made up by a side-plank; .... between midship thwarts to be filled by six air-casks or water-breakers, the bilge below platform to be filled with cork.' The 'collapsing boats,' invented by the Rev. J. S. Berthon of Fareham, are particularly useful on board ship, to act as life-boats on emergencies; when folded up, they occupy a space of only one-sixth of their width when open. They are stowed outside the ship's bulwarks with strappings. When the boat is allowed to fall with its weight upon slings attached to its gunwale, it opens instantaneously without any manual labour, and is kept permanently open. The framework is of wood, with fastenings of metal, and is formed of longitudinal timbers running the whole length; they are hinged to each other, and to the top of the stern and stern-post. When opened, they extend two skins of a strong water-tight material; the outer skin being attached to the outer edges of the timbers, and the inner to the inner edges. A number of water-tight compartments are thus formed, corresponding in number to the air-spaces between the timbers; these air-cells expand and become filled with air as the boat opens.

Next in importance to having an efficient ship's life-boat, is that of a plan by which it can be readily and safely lowered from the ship's side. Want of good plans to attain this has frequently led to lamentable loss of life. The sad tragedy of the burning of the steam-ship *Amazon*, and the loss of life occasioned by this deficiency, gave a great impulse to invention in this department. The plan best known, and said to be the most efficient for lowering ships' boats, is that of Lacon's, which was a result of this impulse. The principal feature is the employment of a friction-brake, by which one man can regulate the rate of descent to any degree of speed. Although highly recommended by first-rate authorities, it is unfortunate that the cost of erecting the apparatus is such as to exclude its being used generally. The plan adopted by whalers consists in strong davits, a good purchase of two large threefold blocks with swivel hooks into a shackle at the top of the stern and stern-post.

Captain Manby's Apparatus.—Next to the life-boat, the most important inventions for the humane end of saving lives at sea have been those of Captain Manby, which have for their object *the throwing of a rope from the shore to the ship, or from the ship to the shore.* Boats with the crews could obviously be thus drawn ashore in almost any circumstances. A cannon-shot affixed to a rope, and projected from a piece of ordnance over a stranded vessel, seemed a practicable mode of establishing the communication. Simple as the idea was, many difficulties were in the way, and were only removed by patient and long-continued trials. These resulted, however, in crowning the inventor's efforts with complete success, affording him the great gratification of knowing that his plans were useful in saving many lives. The original plan of throwing a rope from the shore to the stranded vessel, then to be seized by the crew, was obviously capable of great improvement. The first point to be attended to was a means of attaching the rope to the ship without the intervention of the crew, who might be incapable of affording assistance through cold or fatigue. This was effected by having a quadruple barb attached to the shot, which fastened to the rigging, and by means of which a boat could be hauled from the shore to the ship. The third point was to enable the position of the vessel to be accurately ascertained in the dark; this being attained by throwing up a fire-ball filled with stars, which, on the ball bursting, took fire, and threw out a great light.

Floats and Life-buoys are also useful on board ship. The floating life-buoy invented by Lieutenant Cook of Plymouth is in common use. It consists of two casks connected by a bar between them. The buoy is suspended to the stern of the vessel by a chain; a trigger ignites a port-fire previous to being lowered into the water; the light thus afforded is a guide at once to the person who has fallen overboard, and to the boat sent out in search of him. Since the introduction of air-tight and waterproof materials, a great variety of floats have been introduced; these are in the form of belts, mattresses, capes, waistcoats, and are capable of being immediately filled with air, which gives them buoyancy. Cork, in a variety of shapes and methods of manufacture, is also used as a material for floats.



ARCHITECTURE.

ARCHITECTURE, or the art of planning and raising edifices, appears to have been among the earliest of human inventions. The first habitations of men were such as nature afforded, with but little labour on the part of the occupant, yet sufficient to supply his simple wants—grottos, huts, and tents. In early times, the country of Judea, which is mountainous and rocky, offered cavernous retreats to the inhabitants, who accordingly used them instead of artificial places of shelter. From various passages in Scripture, it appears that these caves were often of great extent, for in the sides of the mountain of Engedi, David and 600 men concealed themselves. In the course of time, art was employed to fashion the rude cavernous retreats, and to excavate blocks by which rude buildings were composed in more convenient situations. The progress of architecture, however, from its first dawn, differed in almost every different locality. Whatever rude structure the climate and materials of any country obliged its early inhabitants to adopt for their temporary shelter, the same structure, with all its prominent features, was afterwards kept up by their refined and opulent posterity.

After mankind had learned to build houses, they commenced the erection of temples to their gods, and these they made still more splendid than private dwellings. Thus architecture became a fine art, which was first displayed on the temples, afterwards on the habitations of princes and public buildings, and at last became a universal want in society.

Traces of these eras of advancement in the art of erecting buildings are found in various quarters of the globe, especially in Eastern countries, where the remains of edifices are discovered of which fable and poetry can alone give any account. The most remarkable of these vestiges of a primitive architecture are certain pieces of masonry found in Greece, Asia Minor, and in the island of Sicily, called the works of the Cyclops, an ancient and fabulous race of giants, mentioned by Homer in his *Odyssey*. By whom these gigantic walls were actually erected, is unknown, though it is most probable that they were raised by the Pelasgians—the predecessors or ancestors of the later Greeks. A gradual progress, indeed, may be traced in them, from the extreme of rudeness, to a degree of symmetry that indicates an approach to the elegance of Grecian architecture. Mr Hamilton divides these so-called Cyclopean structures into four eras:—1. Those such as the walls at Tyrins and Mycene, in which the blocks are of various sizes, having smaller stones in their interstices; 2. Those at Julis and Delphi, formed of irregular stones, without courses, their sides fitting to each other; 3. Where the stones are in courses of the same height, but of unequal length, as in Bœotia, Argolis, and Phocis; 4. Where the blocks are of various heights, and always rectangular, as in Attica.

Of the progressive steps from comparative rudeness to elegance of design, history affords no certain account, and we are often left to gather facts from merely casual notices. The most ancient nations known to us, among whom architecture had made some progress, were the Babylonians, whose most celebrated buildings were the temple of Belus, the palace and the hanging-gardens of Semiramis; the Assyrians, whose capital, Nineveh, was rich in splendid buildings; the Phœnicians, whose cities, Sidon, Tyre, Aradus, and Sarepta, were adorned with equal magnificence; the Israelites, whose temple was considered as a wonder of architecture; the Syrians; and the Philistines.

Of the peculiarities of the styles adopted by those nations, we have no definite information, with the exception of that of the Assyrians at Nineveh. The researches of recent travellers, as Layard and Botta, have enabled us to form a clear notion of the characteristics of this interesting era of the art. A notice of these the reader will find in its proper place in the present paper.

To the researches of Mr Robert Fergusson, we are indebted for works illustrative of the peculiarities of Indian architecture, and for a series of beautiful illustrations of the caves in the islands of Elephanta and Salsette, near Bombay, and of the rock-cut temples in the mountains of Ellora, near Aurungabad. These temples may be reckoned among the most stupendous ever executed by man. The circuit of the excavations is about six miles. The temples are 100 feet high, 145 feet long, and 62 feet wide. They contain thousands of figures, appearing, from the style of their sculpture, to be of ancient Hindoo origin. Everything about them, in fact, indicates the most persevering industry in executing one of the boldest plans. In the chief temple, the vault is supported by several rows of columns, which form three galleries, one above the other. Twenty-four colossal monoliths, representing Indian gods, are placed in separate divisions, the sculpture of which, though on the whole rude, shews in some parts an advanced period of art, and a certain development of taste. In many respects, Hindoo architecture bears a striking resemblance to the Egyptian (hereafter described), more especially in the pyramidal character of its masses, in its excavations and cavern-temples, as well as those which, though presenting the forms of constructed buildings, are yet hollowed out of the rock. The Egyptian, however, is more simple and severe, and less loaded with incongruous, and often grotesque ornament.

Of late years, travellers have made known the remains of an architecture and sculpture, not very dissimilar to those of the ancient Hindoos, in certain districts of Central America, believed to be the execution of a people anterior to those Mexicans who existed at the period of the invasion of Cortes. Our limited space precludes any detail of those curious structures, which consist of temples, palaces, triumphal and religious monuments—all of which are covered with rude but elaborate sculptures, and mark the existence of a luxurious and wealthy, but semi-barbarous people.*

ASSYRIAN ARCHITECTURE.

One of the most prominent features of Assyrian architecture is the huge artificial mounds upon which the buildings are erected. These mounds, varying in height from thirty to forty feet, rise at once from the surrounding level plain, and seem originally to have been dictated by a desire to render the structures capable of resisting an attack, or probably, as some have conjectured, by religious motives. The buildings which crowned these mounds were approached by inclined planes, and by broad flights of steps cut at intervals in the terraces. The face of the terraces appears to have been at once finished and strengthened by a layer of solid limestone slabs; the material of which the mounds were

* Of these new-world antiquities, the reader will find an ample and most interesting account (accompanied by illustrations) in Stephens's *Yucatan* and *Central America*—published at New York respectively in 1841 and 1843.

constructed—in some cases, rubbish, in others, sun-dried bricks—requiring this protection against the effects of the climate. No margin was left round the building, but the wall was brought up to the extreme edge of the mound or terrace. The buildings themselves were of a very peculiar character; the outline of the structure was nearly square, and contained open courts or large halls, round which were placed chambers of great length in proportion to their breadth, the latter being often twenty-five, while the former was 200 feet. Two façades were usually given to the structure thus arranged, the three entrances with which each façade was furnished being guarded by those colossal figures the forms of which are now comparatively well known, and of one of which we here give an illustration. 'The two side gateways,' says Mr

Fig. 1.

Layard, in describing the Assyrian Court in the Crystal Palace, 'in the more splendid edifices, were flanked by similar figures; and between them and the centre entrance were pairs of the same winged monsters, of somewhat smaller size, placed back to back, and separated by a colossal human figure, usually represented as strangling a lion. These intervening bulls had the human heads turned sideways, so as to look outwards from the front of the building. Each bull was, moreover, flanked by a colossal figure of a deity or priest presenting a pine cone. Thus the south-eastern part of Sennacherib's palace at Kouyunjik consisted of two human-headed bulls—the largest being about nineteen feet high—and of six gigantic human figures, occupying altogether a space of no less than 180 feet. It was continued on either side by sculptured walls, which completed the whole façade.' The sculptured walls here alluded to were of great thickness, constructed of dried bricks, and faced with large slabs of alabaster, sculptured with various subjects. The floors of the edifices were also covered with similarly sculptured slabs, or else with square bricks, containing on their under side the name of the king who constructed the edifice; hence the value of a brick excavated from one of the mounds of the plains of Mesopotamia, as a historical record of rare value. Scroll-work was, however, often substituted for figures on the floor-slabs.

It is these sculptured slabs, forming the panelling of the walls and the pavement of the floors, that possess such an interest, in an archæological point of view, as from them we can learn the daily life of the Assyrians, how they fought their battles, and how cities were besieged and won. The result of the discoveries at Nineveh and elsewhere, has as yet made clear only the method of construction up to the level of the sculptured slabs which lined the walls. How the upper part was constructed—if upper part there were—is matter of pure conjecture. Should the reader wish to ascertain on what these conjectures have been founded, and how ingeniously they are applied to the restoration of Assyrian buildings in the Crystal Palace at Sydenham, we refer him to the interesting little volume forming part of the Crystal Palace Library, entitled the *Assyrian Court*, by H. Austen Layard—or to the more elaborate dissertations in the first volume of Mr Fergusson's valuable *Illustrated Hand-book of Architecture.*

On the relation of Assyrian architecture to Grecian, Mr Fergusson remarks: 'Until the discoveries in Assyria were made, half the history of the architecture of Greece was a riddle and inexplicable mystery. Now all is clear; and with Egypt on the one hand, and Assyria on the other, we are enabled to trace every feature to its source. These two stand, and probably will ever stand, as the primitive styles of the human race, essentially distinct in all their more important features, borrowing very little from each other, but each working out its own objects independently of the other. It seems absolutely hopeless to look for anything anterior to the style of Egypt, which can have had any influence upon it; and so far as we can see, nearly as idle to attempt to find in Asia anything that can have influenced the architectural style of the great Assyrian empire.' On some slabs, which are in a particularly excellent state of preservation, there are sculptures in high relief, in which the horses—apparently of the Arabian breed—are equal to examples of Greek art; and the decorations on the dresses of the kings and other personages, are so fine and well executed, as to resemble Chinese cutting in ivory. There is one very remarkable object on one of the slabs; namely, a perfect centaur, as that conception was represented by the Greeks, with the body of a man united to the body and four feet of the beast, and not merely a human head united to the body of the beast by a short neck, as is the case in most Assyrian figures of that kind.

EGYPTIAN ARCHITECTURE.

The elementary features of Egyptian architecture were chiefly as follows:—1. Their walls were of great thickness, and sloping on the outside. This feature is supposed to have been derived from the mud-walls, mounds, and caverns of their ancestors. 2. The roofs and covered-ways were flat, or without pediments, and composed of blocks of stone, reaching from one wall or corner to another. 3. Their columns were numerous, close, short, and very large, being sometimes ten or twelve feet in diameter. They were generally without bases, and had a great variety of capitals, from a simple square block, ornamented with hieroglyphics or faces, to an elaborate composition of palm-leaves, not unlike the Corinthian capital. 4. They used a sort of concave entablature or cornice, composed of vertical flutings or leaves, and a winged globe in the centre. 5. Pyramids, well known for their prodigious size, and obelisks, composed of a single stone often exceeding seventy feet in height, are structures peculiarly Egyptian. 6. Statues of enormous size, sphinxes carved in stone, and sculptures in outline of fabulous deities and animals, with innumerable hieroglyphics, are the decorative objects which belong to this style of architecture.

The main character of Egyptian architecture is that of great strength with irregularity of taste. This is observable in the pillars of the temples, the parts on which the greatest share of skill has been lavished. In the examples that follow, it may be noticed that sturdiness is the prevailing characteristic. The design has been the support of a great weight, and that without any particular regard to proportion or elegance either as a whole or in parts. When assembled in rows or groups, the columns had an imposing effect, because, from their height and thickness, they filled the eye, and induced the idea of placid and easy endurance. 'Compared with Greek architecture, the Egyptian,' says a recent writer, 'is deficient in beauty, grace, variety, and unity. Powerful and imposing as must have been its effect, combined with its sculptural and pictorial decorations,

its avenues of sphinxes, obelisks, and gigantic statues, yet is there something so fixed, monotonous, and conventional, as to impress the mind with a conviction

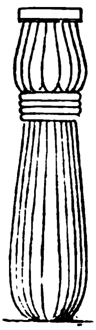


Fig. 2.

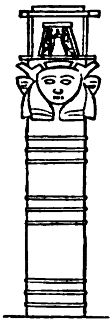

Fig. 3.

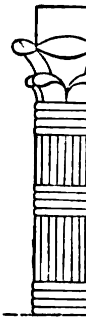

Fig. 4.

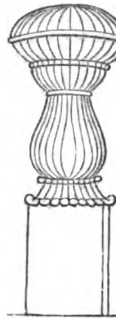

Fig. 5.

that it was unchangeable and incapable of improvement.' In fig. 6, which represents the exterior of a temple, this simple and imposing character is conspicuous. But while the Egyptians thus raised temples and monuments which in strength, solidity, and vastness of dimensions far outstrip those of all other nations,

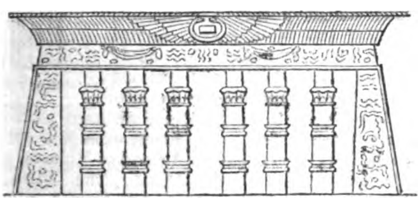

Fig. 6.

yet in street and domestic architecture they were all but utterly deficient. Their streets, if worthy of the name, were narrow and irregular; the generality of their dwellings were mere huts, built of sun-dried bricks, formed of mud and chopped straw; and only among the higher classes was there anything like the enjoyment of a house possessing the elements of elegance or comfort. According to the delineations of Mr Wilkinson, their ordinary houses occupied three sides of a court-yard, which was separated from the street by a wall; while large mansions were detached, having entrances in their several sides, with doors very similar to those of their temples.

GRECIAN STYLE.

From Egypt the architectural art spread to Greece, where it passed from the gigantic to the chaste and elegant. There is no doubt the earliest Greek temples were constructed of wood, the upright supports being united at the top by horizontal lengths, corresponding with the epistylium or architrave. The period during which Greek architecture flourished in the greatest perfection was that of Pericles, about 440 years before Christ, when some of the finest temples at Athens were erected. After this, it declined with other arts, and was carried to Rome, where, however, it never attained the same high character. The Grecian temples were built chiefly of marble, and surrounded or decorated with columns, and had a pleasing effect when situated amidst groves of trees or other kinds of natural scenery; and as the roofs were open to the sky, the beauty of the structures was not deformed by formal rows of windows, such as are now common in modern edifices. Before describing the various orders of Grecian and Roman architecture, it will be advantageous to explain the terms ordinarily employed in reference to the component parts of buildings.

Explanation of Terms.

The *front* or façade of a Greek temple made after the ancient models, or any portion of it, presents four parts occupying different heights (see fig. 8)—namely, the stylobate, or pedestal; the column; the entablature; and the pediment: an order is complete without the pediment. The *pedestal* is the lower part, usually supporting a column; the single pedestal is wanting in most antique structures, and its place supplied by a *stylobate;* the stylobate is either a platform with steps, or a continuous pedestal supporting a row of columns. The lower part of a finished pedestal is called the *plinth*, the middle part is the *dado* or *die*, and the upper part, the *cornice* of the pedestal or *surbase*. The *column* is the middle part, situated upon the pedestal or stylobate. It is commonly detached from the wall, but is sometimes buried in for a portion of its diameter, often as much as half, and is then said to be 'engaged.' *Pilasters.*—The Greeks employed *antæ*, which are flat projecting surfaces attached to the walls of the cells of the temple to receive the ends of the architrave. They were even on the surface, not being fluted: the capital was different from that of the column. The Romans employed pilasters in the place of the Greek antæ, and proportioned them the same as the columns with capitals, bases, and fluted shafts. The lower part of a column, when distinct, is called the *base;* the middle or longest part is the *shaft;* and the upper or ornamented part is the *capital.* The swell of the column is called the *entasis;* the height of columns is measured in diameters of the column itself, taken always at the base of the shaft; the *entablature* is the horizontal continuous portion which rests upon the top of a row of columns; the lower part of the entablature is called the *architrave* or *epistylium;* the middle part is the *frieze*, which, from its usually containing sculpture, was called *zophorus* by the ancients; the upper or projecting part is the *cornice;* the *pediment* is the triangular face produced by the extremity of a roof; the middle or flat portion enclosed by the cornice of the pediment is called the *tympanum*. Pedestals for statues, erected on the summit and extremities of a pediment, are called *acroteria.* An *attic* is an upper part of a building, terminated at top by a horizontal line instead of a pediment, and may be plain or divided by pilasters the height of the attic.

The different *mouldings* in architecture are described from their sections, or from the profile which they present when cut across. Of these, the *torus* is a convex moulding, the section of which is a semicircle, or nearly so; the *astragal* is like the torus, but smaller; the *ovolo* or *echinus* is convex, but its outline is only the quarter of a circle; the *scotia* is a deep concave moulding; the *cavetto* is also a concave, and occupying but a quarter of a circle; the *cymatium* is an undulated moulding, of which the upper part is concave, and the lower convex; the *ogee* or *talon* is an inverted cymatium; the *fillet* is a small square or flat moulding.

A distinguishing characteristic of Roman mouldings is that they are accurately circular, so that they can be struck from a centre; while Greek mouldings form less simple curves, and for the most part must be drawn with a steady hand.

In architectural measurement, a diameter means the width of a column taken at the base; a module is half a diameter; and a minute, the sixtieth part of a diameter.

In representing edifices by drawings, architects make use of the plan, elevation, section, and perspective. The plan is a map or design of a horizontal surface, shewing the ichnographic projection or groundwork, with the relative position of walls, columns, doors, &c. The elevation is the orthographic projection of a front, or

vertical surface; this being represented, not as it is actually seen in perspective, but as it would appear if seen from an infinite distance (fig. 8). The section shews the interior of a building, supposing the part in front of an intersecting plane to be removed (fig. 21). The perspective shews the building as it actually appears to the eye, subject to the laws of scenographic perspective (fig. 28). The three former are used by architects for purposes of admeasurement; the latter is used also by painters, and is capable of bringing more than one side into the same view, as the eye actually perceives them. As the most approved features in modern architecture are derived from buildings which are more or less ancient, and as many of these buildings are now in too dilapidated a state to be easily copied, recourse is had to such imitative restorations, in drawings and models, as can be made out from the fragments and ruins which remain. In consequence of the known simplicity and regularity of most antique edifices, the task of restoration is less difficult than might be supposed. The groundwork, which is commonly extant, shews the length and breadth of the building, with the position of its walls, doors, and columns. A single column, whether standing or fallen, and a fragment of the entablature, furnish data from which the remainder of the colonnade and the height of the main body can be made out and restored.

Grecian temples are well known to have been constructed in the form of an oblong square, or parallelogram, having a *colonnade* or row of columns without, and a walled *cell* within. The part of the colonnade which formed the front portico was called the *pronaos*, and that which formed the back part the *posticus*. There were, however, various kinds of temples, the styles of which differed: thus, the *prostyle* had a row of columns at one end only; the *amphiprostyle* had a row at each end; the *peripteral* had a row all round; the *dipteral* had a double row all round; and the *psuedo-dipteral* had the inner range of columns of the flanks attached to the walls.

The theatre of the Greeks, which was afterwards copied by the Romans, was built in the form of a horseshoe, being semicircular on one side and square on the other. The semicircular part, which contained the audience, was filled with concentric seats, ascending from the centre to the outside. In the middle or bottom was a semicircular floor, called the *orchestra*. The opposite or square part contained the actors. Within this was erected, in front of the audience, a wall, ornamented with columns and sculpture, called the *scena*. The stage or floor between this part and the orchestra was called the *proscenium*. Upon this floor was often erected a movable wooden stage, called by the Romans *pulpitum*. The ancient theatre was open to the sky, but a temporary awning was erected to shelter the audience from the sun and rain.

Orders.

Aided, doubtless, by the examples of Egyptian art, the Greeks gradually improved the style of architecture, and originated those distinctions which are now called the 'Orders of Architecture.' By this phrase is understood certain modes of proportioning and decorating the column and its entablature. They were in use during the best days of Greece and Rome for a period of six or seven centuries. They were lost sight of in the dark ages, and again revived by the Italians at the time of the restoration of letters. The Greeks had three orders—called the Doric, Ionic, and Corinthian. These were adopted and modified by the Romans, who added two others—the Tuscan and Composite.

Doric.—This is the earliest of the Greek orders, and we see in it a noble simplicity on which subsequent orders were founded. Compared with the best of the Egyptian models, it exhibits a great advance in purity of taste. From the remains of ancient art, it is found that the Doric varied in its proportions. The column, in its examples at Athens, is about six diameters in height; but in those of older date, as those at Pæstum, it is only four or five. One of the most correct examples is that given in fig. 7. The shaft of the Doric column had no base, ornamental or otherwise, but rose directly from the smooth pavement or stylobate. It had twenty flutings, which were superficial, and separated by angular edges. The perpendicular had an entasis, or swelling outline. The Doric capital was plain, being formed of a few annulets or rings, a large echinus, and a flat stone at top called the *abacus*. The architrave was plain; the frieze was intersected by oblong projections called triglyphs, divided into three parts by vertical furrows, and ornamented beneath by *guttæ*, or drops. The spaces between the triglyphs were called *metopes*, and commonly contained sculptures. The sculptures, representing Centaurs and Lapithæ, carried by Lord Elgin to London, were metopes of the Parthenon, or temple of Minerva, at Athens. The cornice of the Doric order consisted of a few large mouldings, having on their under side a series of square sloping projections, resembling the ends of rafters, and called *mutules*. These were placed over both triglyphs and metopes, and were ornamented on their under side with circular guttæ. The Romans, in adopting the Doric, greatly spoiled its simplicity and grandeur by unduly lengthening the shaft, and making other tasteless alterations. To have a just idea of the Doric, therefore, we must go back to the pure Grecian era. The finest examples are the temple of Theseus, and that of Athena or Minerva, called the Parthenon (fig. 8) at Athens. The Parthenon, which is now a complete ruin, has formed a model

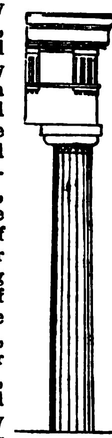

Fig. 7.

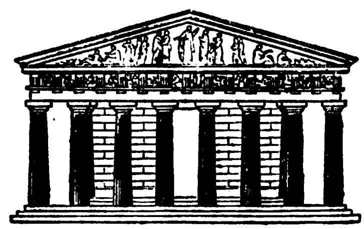

Fig. 8.—Façade of the Parthenon.

in modern architecture. It was built by the architect Ictinus, during the administration of Pericles, and its decorative sculptures are supposed to have been executed under the direction of Phidias. The platform or stylobate consists of three steps, the uppermost of which is 227 feet in length, and 101 in breadth. The number of columns is eight in the portico of each front, and seventeen in each flank, besides which there is an inner row of six columns at each end of the cell. The proportional height of the columns is five diameters and fifty-six minutes, and they diminish thirteen minutes in diameter from bottom to top. The sculpture of the frieze of the peristyle, represented the combats of the Centaurs and Lapithæ; those of the eastern pediment represented the fabulous birth of Minerva; and those on the western, the contests between the goddess and Neptune for the right of presiding over the city. The interior was divided in unequal parts by a cross-wall; the smaller portion was called the *opisthodomus*, where the public treasure was kept; in the larger division stood the famous statue of Minerva, wrought in ivory and gold, by Phidias. The building was destroyed by the explosion of a bomb-shell during the siege by the Venetians in 1687.

Speaking of these splendid objects of art, a modern authority observes: 'Of their effect it is impossible to form a competent idea without seeing one. And whence, it may be asked, does this interest arise? From their simplicity and harmony: simplicity, in the long unbroken lines which bound their forms, and the breadth and boldness of every part; harmony, in the evident fitness of every part to all the rest. The entablature, though massive, is fully upborne by the columns, whose spreading abaci receive it, and transmit the weight downwards by the shafts, which rest on a horizontal and spreading basement; the magnitude of every part being determined by the capacity of the sustaining power. Besides graceful and elegant outline, and simple and harmonious forms, these structures possess a bewitching variety of light and shade, arising from the judicious contour and arrangement of mouldings, every one of which is rendered effective by the fluting of the columns, and the peculiar form of the columnar capital, whose broad square abacus projects a deep shadow on the bold ovolo, which mingles it with reflections, and produces on itself almost every variety. The play of light and shade, again, about the insulated columns, is strongly relieved and corrected by the deep shadows on the walls behind them; and in the fronts, where the inner columns appear, the effect is enchanting. For all the highest effects which architecture is capable of producing, a Greek peripteral temple of the Doric order is perhaps unrivalled.'

Ionic.—In this order, the shaft begins to lengthen, and to possess a degree of ornament, but still preserving great simplicity of outline. In the best examples, as represented in fig. 9, the column was eight or nine diameters in height. It had a base often composed of a torus, a scotia, and a second torus, with intervening fillets. This is called the Attic base. Others were used in different parts of Greece. There is a remarkable distinction in the form of the flutings to the shafts of the Greek Doric and Ionic orders; the divisions of the flutes in the Doric being brought to an arris, or edge, while in the Ionic, the divisions of the flutes are 'fillets.' The capital of this order consisted of two parallel double scrolls, called *volutes*, occupying opposite sides, and supporting an abacus, which was nearly square, but moulded at its edges. These volutes have been considered as copied from ringlets of hair, or perhaps from the horns of Jupiter Ammon. When a column made the angle of an edifice, its volutes were placed, not upon opposite, but on contiguous sides, each fronting outwards. In this case, the volutes interfered with each other at the corner, and were obliged to assume a diagonal direction. The Ionic entablature consisted of an architrave and frieze, which were continuous or unbroken, and a cornice of various successive mouldings, on the lower portion of which was often an angular member, divided by deep cuttings into 'dentels or square teeth: this member is called the dentel band.' The examples at Athens of the Ionic order were the temple of Erectheus and the temple on the Ilissus, both now destroyed. Modern imitations are common in public edifices.

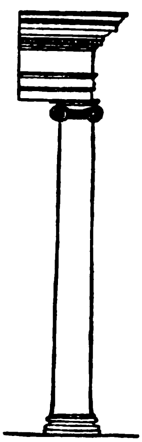

Fig. 9.

Corinthian.—This was the lightest and most highly decorated of the Grecian orders (fig. 10). The base of the column resembled that of the Ionic, but was more complicated. The shaft was often ten diameters in height, and was fluted like the Ionic. The capital was shaped like an inverted bell, and covered on the outside with two rows of leaves of the plant acanthus, above which were eight pair of small volutes. Its abacus was moulded and concave on its sides, and truncated at the corners, with a flower on the centre of each side. The entablature of the Corinthian order resembled that of the Ionic, but was more complicated and ornamented, and had, under the cornice, a row of large oblong projections, bearing a leaf or scroll on their under side, and called *modillions.* No vestiges of this order are now found in the remains of Corinth, and the most prominent example at Athens is in the choragic monument of Lysicrates. The Corinthian order was much employed in the subsequent structures of Rome and its colonies. The finest Roman example of this order is that of three columns in the Campo Vaccino at Rome, which are commonly considered as the remains of the temple of Jupiter Stator. This example has received the commendation of all modern artists, yet has seldom been executed in its original form. This is probably owing to its excessive richness and delicacy, which render its adoption very expensive; and perhaps the modification of it by Vignola is preferable to the original, possessing a sufficient enrichment without the excessive refinement of the other. In this order, the base is one module in height; the shaft, sixteen modules twenty minutes; and the capital, two modules ten minutes—thus giving ten diameters to the whole column. The architrave and frieze are each one module twelve minutes in height, and the cornice two modules and nine minutes. The cornice is distinguished by modillions interposing between the bed-mouldings and corona; the latter is formed by a square member surmounted by a cymatium, supported by a small ogee: the former is composed of dentels, supported by the ovolo, and covered by the cyma reversa. When the order is enriched, which is usually the case, these mouldings, excepting the cymatium, are all sculptured: the column is also fluted, and the channels are sometimes filled to about a third of their height with cablings, which are cylindrical pieces let into the channels. When the column is large, and near the eye, these are recommended as strengthening them, and rendering the fillets less liable to fracture; but when they are not approached, it is better to leave the flutes plain. They are sometimes sculptured, but this should only be in highly enriched orders.

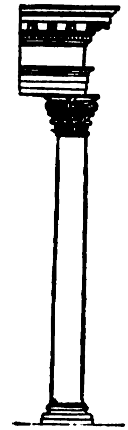

Fig. 10.

The flutes are twenty-four in number, and commonly semicircular in their plan in the Roman examples. The Corinthian base is similar to that of the Composite order, excepting that two astragals are employed between the scotiæ instead of one; but the Attic is usually employed for the reasons before assigned.

'The Corinthian order,' says Sir William Chambers, 'is proper for all buildings where elegance, gaiety, and magnificence are required. The ancients employed it in temples dedicated to Venus, to Flora, Proserpine, and the nymphs of fountains, because the flowers, foliage, and volutes with which it is adorned, seemed well adapted to the delicacy and elegance of such deities. Being the most splendid of all the orders, it is extremely proper for the decoration of palaces, public squares, or galleries and arcades surrounding them; and on account of its rich, gay, and graceful appearance, it may with propriety be used in theatres, in ball or banqueting rooms, and in all places consecrated to festive mirth or convivial recreation.'

Caryatides.—The Greeks sometimes departed so far from the strict use of the orders, as to introduce statues in the place of columns, to support the entablature. Statues of slaves, heroes, and gods appear to have been employed occasionally for this purpose. The principal specimen of this kind of architecture which remains is in a portico called Pandroseum, attached to the temple

of Erectheus at Athens, in which statues of Carian females, called Caryatides, are substituted for columns. One of these statues has been carried to London.

ROMAN STYLE.

Strictly speaking, Roman architecture possessed little originality; it was founded on copies of the Greek models, and these were modified to suit circumstances and tastes. The Roman examples of Doric and Ionic had very different proportions from the Greek. The number of orders was augmented by the addition of the Tuscan and Composite; the former being the Doric stripped of its distinctive ornaments; the latter, a combination of the Ionic and Corinthian. The distinguishing feature of the Roman style is boldness of execution and elaborate profusion of ornament—as by their adaptation of the principles of the arch, they were enabled to rear structures of greater extent and complexity of design. In the Coliseum, for example, columns and arches are piled upon columns and arches in the interior, and must have struck the beholder with wonder and astonishment; yet in the external plan, the building has been pronounced 'a gigantic illustration of architectural blunders.'

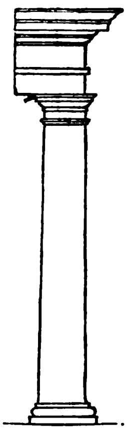

Fig. 11.

Tuscan.—This order is not unlike the Doric, and is chaste and elegant. As represented in fig. 11, the shaft had a simple base, ornamented with one torus, and an astragal below the capital. The proportions were seven diameters in height. Its entablature, somewhat like the Ionic, consisted of plain running surfaces. There is no vestige of this order among ancient ruins, and the modern examples of it are taken from the descriptions of Vitruvius.* The general effect is strength with simplicity, and the order is considered to be well adapted for such buildings as prisons, public halls, and inferior parts of edifices.

Composite.—This order, as the name imports, is a compound of other orders—namely, the Corinthian and Ionic (fig. 12). The proportion and distribution of its parts do not differ much from those of the Roman Corinthian. It would appear from these efforts, as well as from all subsequent attempts, that the Greeks attained the highest state of improvement of which their style was susceptible, and that, consequently, all schemes to execute something better must prove abortive. The higher class of Roman architects were convinced of this fact, and very judiciously held to the Corinthian order in all their finest buildings, both in Rome and in the provinces. Thus the Corinthian prevails among the celebrated ruins of Palmyra and Balbec, and other great cities founded by Roman provincials.

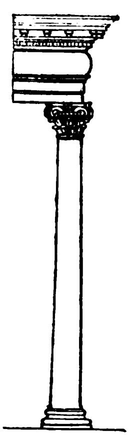

Fig. 12.

The temples of the Romans sometimes resembled those of the Greeks, but often differed from them. The Pantheon, which is the most perfectly preserved temple of the Augustan age, is a circular building, lighted only from an aperture in the dome, and having a Corinthian portico in front. Though stripped of its external ornaments, to furnish materials to decorate the modern cathedral of St Peter's, it is still incomparably the finest. It is a perfect circle, of 180 feet in diameter. 'Its beauty,' says Forsyth, 'consists in its admirable proportions; and its portico, 110 feet in length by 44 in depth, supported by sixteen Corinthian columns of Oriental granite, has a most majestic appearance. Its portal is more than faultless: it is positively the most sublime result that was ever produced by so little architecture.'

The amphitheatre differed from the theatre in being a completely circular, or rather elliptical building, filled on all sides with ascending seats for spectators, and leaving only the central space, called the *arena*, for the combatants and public shows. The Coliseum is a stupendous structure of this kind. It consists of a vast ellipse, the length of the longest diameter being 620, and that of the shortest 513 feet, so that it covers about five and a quarter acres of ground! The longest diameter of the arena has been variously given at from 287 to 300, and the shortest at from 180 to 190 feet; the space between the arena and the outer wall (from 160 to 167 feet) being occupied by the walls, corridors, and seats, that rose, tier above tier, from the wall round the arena nearly to the top of the outer wall. The latter, which is about 179 feet in height, consists of three rows of vaulted arches, rising one above another, exclusive of which it had, when perfect, upper works of wood. This colossal amphitheatre is said to have had seats for 87,000 spectators, and standing-room for 20,000 more! Belonging to the same class of buildings were the circuses, of which Rome had at one time no fewer than fifteen. Of these, the chief was the Circus Maximus, of which there are now no remains, but of whose dimensions we may judge from the statement of Pliny, that it was capable of accommodating 200,000 spectators.

The triumphal arches were commonly solid oblong structures, ornamented with sculptures, and open with lofty arches for passengers below. The edifice of this kind most entire in the present day is the triumphal arch of Constantine at Rome, represented in fig. 13. This structure is ornamental, and far from inelegant, but it contains much that is tasteless, inasmuch as being

Fig. 13.

without meaning; and there is also an undue overloading of embellishment, or at least frittering away in details. Carrying the eye up the columns, and dissecting their individual bearings, we perceive that each may be resolved into the shafting represented on a larger scale in fig. 14, which is evidently anomalous in design, and inconsistent with the dignified simplicity of the pure Grecian models. The arch of Constantine has been copied at Paris, in the structure erected by Napoleon in front of the Tuileries.

The *basilica* of the Romans was a hall of justice, used also as an Exchange or place of meeting for merchants. It was lined on the inside with colonnades of two stories, or with two tiers of columns, one over the other. The earliest Christian churches at Rome were sometimes called *basilicæ*, from their possessing an internal colonnade. The *thermæ*, or baths, were vast structures,

* Vitruvius was a celebrated writer on architecture, who is supposed to have flourished in the time of Julius Cæsar and Augustus. His treatise on architecture was first printed at Venice in 1497. An English translation appeared in 1771. A new translation by Wilkins was published in 1812.

in which multitudes of people could bathe at once. As they now exist, they are an assemblage of naked, half-dilapidated brick-walls, which surprise by their huge size and the extent of ground they cover—those of Caracalla, for example, occupying not less than twenty-eight acres! In the palmy days of Rome, these were fitted not only as hot and cold water baths, but as gymnasia, reading and lecture rooms, gardens, theatres, and the like—being, as a whole, the most gigantic places of recreation ever built in any age or in any country.

ANGLO-NORMAN STYLE.

By Anglo-Norman architecture is understood that style which prevailed in England immediately after the Conquest, and which received the epithet Norman, as coming directly from Normandy. It is considered extremely doubtful if any specimens of the architecture of the Anglo-Saxons before the Conquest are now extant. At all events, the Anglo-Saxon and the Norman were in their essential elements the same, being both only local modifications of the style called Romanesque, which then prevailed in the west of Christendom generally, being derived, along with Christianity, from the later Roman. The principal characteristic of the Norman architecture is the circular arch, springing either from a single column, or from a pier decorated with half columns or light shafts, the evident origin of the clustered pillar of a later date. The walls are so massive as to render buttresses unnecessary. The windows are small in proportion, and generally simple in form, though sometimes

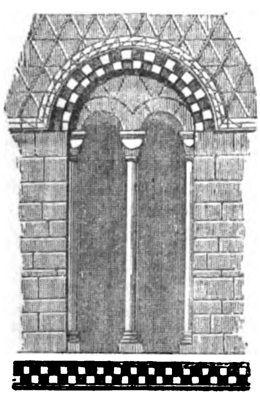

Fig. 14.—Window from Caxton Church.

divided by a column into two lights, within the external arch. In Anglo-Norman works, the greatest display of ornament was lavished on the doorways, which are often deeply recessed, the arch consisting of a succession of enriched bands, one within another.

The peculiarities of the style may be met with in many of the English cathedrals—as, for instance, in those of Norwich, Canterbury, Gloucester, Worcester, &c.; and exemplifications of its external characteristics may also be seen in some of these edifices, and in the White Tower, Tower of London.

GOTHIC OR POINTED STYLE.

The term Gothic is a modern error, which, being now beyond correction, is suffered to remain as the generally distinguishing appellation of the kind of architecture possessing pointed arches. This style, according to some, originated in Germany about the middle of the thirteenth century; according to others, it was introduced by the Crusaders from the East, where it is said to have been known long before that period. Be this as it may, for three centuries after its introduction, it was zealously pursued as the leading fashion for ecclesiastical structures all over Europe. Executed by a class of skilled artisans, who wandered from country to country,* the finest specimens of the pointed style are the cathedrals of Strasburg, Cologne, and Antwerp, and the splendid abbeys of Melrose and Westminster (fig. 15).

Fig. 15.

The origin of the Gothic or pointed arch is one of the disputed points of architecture. Some, as Bishop Warburton, refer it to the accidental interlacings and crossings of the boughs of trees. Other theories, equally fanciful, have been promulgated; but now the opinion seems to be generally held, that the pointed arch had its origin in the intersections of the rounded or circular arches of the Norman architecture—a very common arrangement in this style being a series of arches struck from centres distant from each other by spaces equal to the semi-diameter of the arch. It is, however, worthy of notice, that the recent discoveries amidst the ruins of Nineveh shew that the pointed arch was familiar to the Assyrians—a large sewer with a pointed arch having been met with there. Specimens of the intersecting arches may be met with in some of our old abbeys, as Fountain's Abbey, Kirkstall Abbey, in Yorkshire; the Temple Church, London; St Cross, Winchester, &c.

In England, the transition from the Norman to the pointed style of arch is observed in various old buildings. In the Temple Church, the two arches may be found united, and other specimens may be seen in the church of St Cross, near Winchester; and Fountain's Abbey, Rivaulx Abbey, and Roche Abbey, in Yorkshire.

When the circular arch disappeared, the Early English

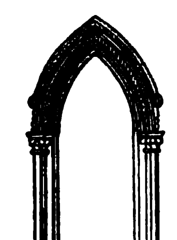

Fig. 16.—York.

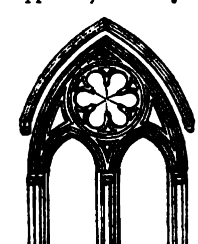

Fig. 17.—Westminster.

Gothic commenced (1189). The windows of this style were at first very narrow in comparison with their

* We here allude to the order or craft of Freemasons, the origin of whose associations may be dated from the ninth or tenth century, and who attained their greatest numerical strength and importance at the introduction of the Gothic or pointed style of architecture. Afterwards the order became a speculative society, unconnected with the practice of architecture, and finally has sunk before the spread of universal intelligence, and a common philanthropy which recognises all men as brothers.

height; they were called lancet-shaped, and were considered very elegant. Two or three were frequently seen together, connected by dripstones, and divided by narrow widths of walling in courses: by degrees the divisions between the window-lights were reduced, and assumed the form of shafts and mouldings. As the style advanced, the same window was divided into several lights, and frequently finished at the top by a light in the form of a lozenge, circle, trefoil, or other ornament. Figs. 16, 17 are two specimens of the windows of this period.

About the year 1300, the architecture became more ornamental, and from this circumstance received the name of the Decorated English Style, which is considered the most beautiful for ecclesiastical buildings. The windows of this style are very easily distinguished: they are divided into several lights by mullions, which are upright or perpendicular narrow shafts, branching out at the top into tracery of various forms, such as trefoils, circles, and other figures. In the accompanying illustration, fig. 18 represents a window of this kind;

Fig. 18.

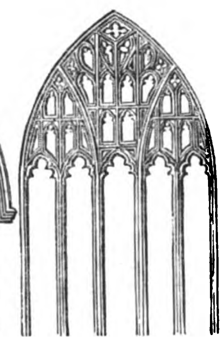

Fig. 19.

fig. 19, from the choir, York, exhibits the transition to what has been called the Perpendicular Style, from the lines of division being upright.

In this third modification of the English Gothic, which is claimed as peculiarly national, ornament after ornament was added, till simplicity disappeared beneath the extravagant additions; and about the year 1380, the architecture became so overloaded and profuse, that it obtained the title of Florid. King's College Chapel, Cambridge, and Henry VII.'s Chapel at Westminster, are considered perfect examples of this style. Many small country churches are built in it; and their size not admitting of much ornament, they are distinguished from structures of a later date by mouldings running round their arches, and generally by a square head over the obtuse-pointed arch of the door. A peculiar ornament of this style is a flower of four leaves, called, from the family reigning at that period, the Tudor Flower.

Definitions of Parts.

Gothic architecture being for the most part displayed in ecclesiastical edifices, it may be of service to explain the usual plan and construction of these buildings. A church or cathedral is commonly built in the form of a cross, having a tower, lantern, or spire erected over the place of intersection. The part of the cross situated towards the west is called the *nave;* the opposite or eastern part is called the *choir*, and within this is the *chancel.* The transverse portion, forming the arms of the cross, is called the *transept*, one limb being called the northern, and the other the southern transept. To the principal figure of a cathedral church are appended subsidiary buildings, as (1) *Lady-chapel;* (2) *Chapter-house;* (3) *Cloisters*, &c.

Generally the nave is larger than the choir. If the nave, choir, and transepts be all of the same dimensions, the form is that of a Greek cross. When the nave is

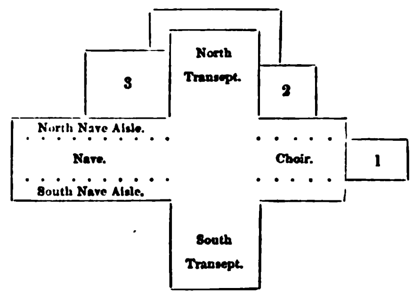

Fig. 20.

longer than the other parts, forming a cross of an ordinary shape, the edifice is said to be in the form of a Latin cross. The spaces or passages between the side-walls and the rows of columns or piers that support the roof, are called *ailes* or *aisles* (wings); a term sometimes extended, improperly, to the middle division of the nave. Originally, the floors of all such edifices were unencumbered with fixed pews or seats, and as the floors were usually of mosaic or tesselated pavement, the effect was exceedingly imposing.

The ceilings of the most important ecclesiastical buildings of this period were executed in stone, formed into all varieties of curves by the intersections of arches

Fig. 21.

from different directions. The intersections are called *groins*, which were in the later examples ornamented with mouldings called *ribs.* The vaulted ceilings are protected on the outside by a timber roof covered with lead. Many churches, however, have the roof-timbers exposed, without any stone or other ceiling beneath. The roof of the central part of the nave and choir is higher than that of the aisles, and the wall of this elevated central part above the aisle-roof is called the *clerestory.* The vaults are most skilfully poised, and their outward thrust is counteracted by a system of *buttresses* outside (fig. 22), which rise by gradations from a broad basis to narrow-pointed *pinnacles.* Slanting braces, called *flying* buttresses, springing from the main buttresses, and spanning the aisle-roof to the clerestory wall, sustain the lateral pressure of the central roof. Any high building erected above the roof is called a *steeple;* if square topped, it is a *tower;* if long and acute, a *spire;* and if short and light, a

lantern. Towers of great height, in proportion to their diameter, are called *turrets.*

The upper edge of a wall, if straight, is called a *parapet;* if indented, a *battlement.* Gothic windows were commonly crowned with an acute arch; they were long and narrow, or if wide, were divided into perpendicular lights by *mullions.* The lateral spaces on the upper and outer side of the arch are called *spandrels;* and the ornaments in the top, collectively taken, are the *tracery.* An *oriel window* projects from the wall, and is supported on a *corbel,* or bracket; a *bay-window* rises from the ground, and is semi-octagonal, or semi-hexagonal, or polygonal in plan; a *wheel* or *rose window* is large and circular; a *corbel* is a bracket or short projection from a wall, serving to sustain a statue, the springing of an arch, &c.; the Gothic term *gable,* indicates the erect end of a roof, and answers to the Grecian pediment, but is generally more acute.

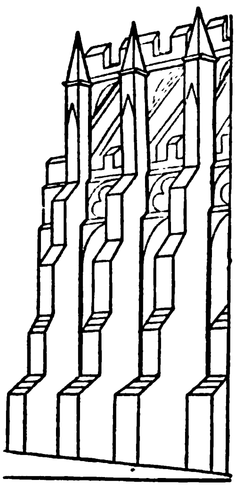

Fig. 22.

The polished tastes of the architects employed in constructing Gothic edifices, led to numerous devices in the form of the pillars. In early examples, the column was single and round, or polygonal in form; which, as the style advanced, was composed of seemingly a cluster of smaller pillars, and this had always the lightest effect; but occasionally the column was given the appearance of several shafts twisted, or of a single shaft with a festoon of flowers twined spirally around it. In the chapel at Roslin there are some highly ornamented pillars of this kind.

The Gothic style of building is more imposing, and more difficult to execute than the Grecian. This is because the weight of its vaults and roofs is upheld at a great height by supporters acting at single points, and apparently but barely sufficient to effect their object. Great mechanical skill is necessary in balancing and sustaining the pressures; and architects at the present day, hampered by principles of economy, find it difficult to accomplish what was achieved by the builders of the middle ages.

ITALIAN STYLE.

After the dismemberment of the Roman Empire, the arts degenerated so far that a custom became prevalent of erecting new buildings with the fragments of old ones, which were torn down for the purpose. This gave rise to an irregular style of building, which continued to be imitated, especially in Italy, during the dark ages. It consisted of Grecian and Roman details, combined under new forms, and piled up into structures wholly unlike the antique originals. Hence the names Græco-Gothic and Romanesque architecture have been given to it.

After this came the *Italian style,* which was professedly a revival of the classic styles of Greece and Rome, but adapted to new manners and wants—a kind of transition from ancient to modern times. Its great master was Andrea Palladio, a Venetian (born 1518—died 1580). This highly accomplished man expelled much of the Græco-Gothic taste, and established in the sixteenth century what may be called a new era in architecture—sometimes styled the Renaissance. The majestic simplicity of the ancient orders was always present to the mind of Palladio, and he has left behind him many beautiful buildings which attest the purity of his taste. The writer in the *Encyclopædia Britannica* thus describes some peculiarities of the Italian style: 'Prostyles being almost unknown in Italian architecture, antæ are not often required. Pilasters, however, are very common—so common, indeed, that they may be called pro-columns, as they are often used as an apology for applying an entablature. They are described as differing from columns in their plan only, the latter being round, and the former square, for they are composed with bases and capitals; they are made to support entablatures according to the order to which they belong, and are fluted and diminished with or without entasis, just as columns of the same style would be. When they are fluted, the flutes are limited to seven in number on the face, which, it is said, makes them nearly correspond with the flutes of columns; and their projection must be one-eighth of their diameter or width when the returns are not fluted; but if they are, a fillet must come against the wall. Pedestals are not considered by the Italo-Vitruvian school as belonging to the orders, but they may be employed with them all, and have bases and surbases or cornices to correspond with the order with which they may be associated. With columnar arrangements, moulded imposts and archivolts are used; the former being made rather more than a semi-diameter of the engaged columns in height, and the latter, exactly that proportion (fig. 23).

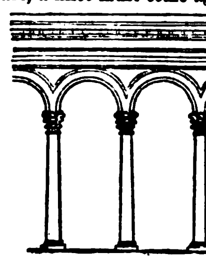

Fig. 23.

'Balustrades are used in various situations, but their most common application is in attics, or as parapets, on the summits of buildings, before windows, in otherwise close-continued stereobates, to flank flights of steps, to front terraces, or flank bridges. Their shapes and proportions are even more diversified than their application; that of most frequent use is shaped like an Italian Doric column, compressed to a dwarfish stature, and consequently swollen in the shaft to an inordinate bulk in the lower part, and having its capital, to the hypotrachelium, reversed to form a base to receive its grotesque form.

'There is considerable variety and beauty in the foliate and other enrichments of an architectural character in many structures in Italy, but very little ornament enters into the columnar composition of Italian architecture. Friezes, instead of being sculptured, are swollen; the shafts of columns are very seldom fluted, and their capitals are generally poor in the extreme; mouldings are indeed sometimes carved, but not often; rustic masonry, ill-formed festoons, and gouty balustrades, for the most part supply the place of chaste and classic ornaments.'

SARACENIC, MOORISH, AND BYZANTINE STYLES.

The Arabs, or Saracens, as they are more usually called, and the Moors, introduced into Spain certain forms of architecture which differed considerably from the Grecian in appearance, though founded on its remains in Asia and Africa. The chief peculiarity of this architecture was the form of the arch: the Saracens are understood to have made it of greater height than width, thus constituting more than half a circle, and being therefore unscientific and comparatively insecure (fig. 24); while the Moorish style was principally distinguished by arches in the form of a horseshoe, or a crescent. The Saracens and Moors, however, were so much one people, that the works of each are not easily pointed out in the present day; both styles were highly ornamented with flowery tracery, called *arabesque,*

the decorations being for the most part sunk below the surfaces of the walls, and highly wrought in various colours of the brightest description and contrast. The pillars supporting the arches were generally slender and elegant. The crescent-like or bulging dome of the Oriental mosque was likewise introduced by the Moorish architects into Europe. It is common, for example, in the church-spires of the Netherlands, having been brought thither by the Spaniards when in possession of the country.

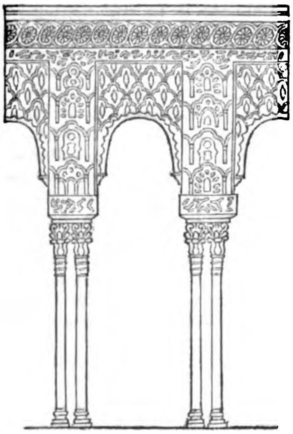

Fig. 24.

We associate with these styles another, which arose at Constantinople, called the Byzantine, likewise formed on the remains of Grecian art, and partaking of a slightly Eastern character. It became known in Western Europe along with the Lombard, another degenerate Grecian style, about the ninth and tenth centuries. The two united received the name of the Lombard-Byzantine, and were employed upon the cathedrals of Worms and Mayence, and several other ecclesiastical structures in Germany. This style is distinguished by small arches resting on connecting central pillars, like the Saracenic, and sometimes there are rows of such arches one above another. Either pure or mixed, the Byzantine style remained in vogue till it was superseded by the Gothic, about the middle of the thirteenth century.

CHINESE STYLE.

Of the date and origin of Chinese architecture, we know nothing, except that it is evidently founded on the type of the Oriental tent—the primitive habitation of the nomadic Tatars, the ancestors of the Chinese. So close, indeed, is the resemblance to the tent, that, from the accounts of travellers, a Chinese city looks like a large permanent encampment. Chinese roofs are concave on the upper side, as if made of canvas instead of wood. A Chinese portico is not unlike the awnings spread over shop-windows in summer-time. The veranda, sometimes copied in dwelling-houses, is a structure of this sort. The Chinese towers and pagodas have concave roofs, like awnings, projecting over their several stories. A representation of this barbaric style of erection is given in fig. 25.

Fig. 25.

Such structures are built with wood or brick; stone is seldom employed. Composed chiefly of timber, the houses of the Chinese are light and gay in appearance—the roofs, porticos, and verandas being generally variegated with different colours and varnishes. 'The law,' says Mr Cleghorn, 'has from time immemorial laid down strict regulations, rigidly enforced, for the plans, dimensions, and materials of the houses of all ranks and castes—from the palaces of the emperor and the princes of the first, second, and third degree, to the habitations of the nobles of the imperial family, the grandees of the empire, the citizens, and all classes.' Hence the extraordinary uniformity remarked by all travellers.

Without the gates of several cities in China, lofty towers or pagodas are erected, which, according to Davis, are of a religious nature, and, like the steeples of churches, were at first attached to temples. The most remarkable of these—and which may be taken as an illustration of the whole—is that of Nankin, called the Porcelain Tower (fig. 26), from the roofs of its different stories or stages being covered with porcelain tiles beautifully painted. It is of an octangular figure, contains nine stories, and is about 200 feet high, raised on a very solid basis of brickwork. The wall at the bottom is at least twelve feet thick; and the building gradually tapers to the top, which forms a sort of spire. It is surrounded by a balustrade of rough marble, and has an ascent of twelve steps to the first floor, from whence one may ascend to the ninth story by very narrow and incommodious stairs. Between every story there is a kind of penthouse on the outside of the tower, from the eaves of which are suspended little brass bells, diminishing in size as they approach the top, and set in motion by the wind. Each story is formed of strong beams of timber, well boarded; the ceilings of the rooms are adorned with paintings; and the light is admitted through lattices of wire. There are likewise niches in the walls filled with idols; and the variety of ornaments that embellish the whole, render it one of the most unique, as it is undoubtedly one of the most beautiful structures in China.

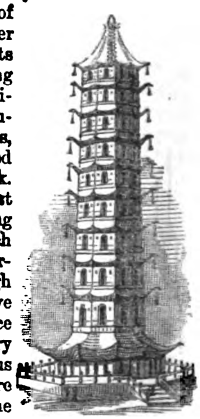

Fig. 26.

TUDOR—ELIZABETHAN—MODERN GOTHIC.

Throughout England may be seen many aged castles, some still in a state of good preservation, but the greater number in ruins, and occupying, with their picturesque remains, the summit of a rising-ground or rocky precipice. These castles are of a style which prevailed during the feudal ages in Europe, and was brought to this country by the Normans, who erected them as fastnesses into which they might retire, and oppress the country at pleasure. The same kind of buildings are also frequent in Scotland, where the barons ruled with the same feudal power as in the southern parts of the island.

The feudal castles in England, like those on the Rhine, consisted for the most part of a single strong tower or keep, the walls of which were from six to ten feet thick, and the windows, only holes of one or two feet square, placed at irregular intervals. The several floors were built on arches, and the roof was flat or battlemented, with notches in the parapet, from which the inhabitants or retainers of the chieftain might defend themselves with instruments of war. The accommodations for living were generally mean, and what would now be called uncomfortable. Around, or in front of the main tower, there was usually a courtyard, protected by a high wall, and the arched entrance was carefully secured by a falling gate or portcullis. Outside, there was in many cases a regular wet ditch or fosse. Castles of greater magnitude consisted of two or more towers and inner buildings, including a chapel and offices for domestics, and horses and other animals. Some of them were on a great scale, and possessed considerable grandeur of design.

As society advanced, and civil tranquillity was established, these military strengths gradually assumed a character of greater elegance, and less the appearance of

defence. The wet ditch disappeared, and was superseded by a lawn or shrubbery. Instead of the drawbridge and portcullis, there was a regular approach and gate of ordinary construction. The windows became larger, and were fitted with glass frames; and stone was abandoned for the greater comfort of wooden floors. Instead also of a bare region around, in which no foe might lurk, gardens were established, and a long avenue of trees led to the front of the modernised mansion. In some instances, the pepper-box turrets at the upper corners of the buildings remained. Of the class of structures that sprung up in this period of transition, which we may refer in England to the fifteenth and sixteenth, and in Scotland, to the seventeenth centuries, there are several highly interesting remains. These edifices of the nobility and gentry were no longer called castles: they took the name of *halls;* and such had attained so great a pitch of magnificence in the reigns of Henry VIII. and Elizabeth, as to have subsequently given a name to a new style—namely, the *Elizabethan.*

'The quadrangular embattled mansion of the last Henries,' says a writer in the *Quarterly Review,* 'affords scope for the display of much grandeur and magnificence, and adapts itself more conveniently to the plan of a modern house. The carved oriel, and deep many-lighted bay-window, often projecting in a multitude of capricious angles and curves, besides the regular octagon, the panelled angled turrets, with richly embossed finials, and the wreathed chimney-shafts, are characteristic beauties of this class of building. The gabled manor-house, together with these ornamental features, admits at the same time of a much greater irregularity of form and outline, so as to accommodate itself to every variety of disposition, and to buildings of every size, from the baronial residence to the parsonage and grange. All the forms which particularly mark the Elizabethan style, may be wrought in the cheapest materials with comparatively little labour; and a small portion of ornamental work, tastefully disposed, is capable of producing very considerable effect. Lastly, the Elizabethan house is distinguished by the number and size of its rectangular and many-mullioned windows, which gave a peculiar lightness and elegance to its several parts. The roof-line may be either horizontal or broken with gables, turrets, and cupolas. In either case, it is enriched with perforated parapets, balustrades, or other architectural devices, while similar embellishments ornament the entrance, and the terraces which connect the building with the garden.'

Fortunately, this light and elegant style of domestic architecture is gradually superseding the bald Græco-Italian style of the eighteenth century. A better taste

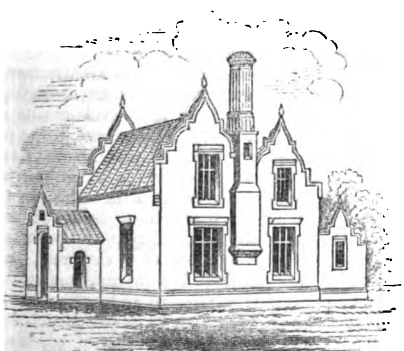

Fig. 27.

is evidently extending itself, particularly as regards the erection of villas, cottages, hunting-seats, gate-lodges, and other rural residences. To these the old English style is peculiarly well adapted. The leading feature of this style applied to cottages is the dispensing with unbroken lines. The house is composed of different parts, projecting at right angles from each other, with also a projecting porch, and the outshot octagonal windows commanding views in three different directions. It also sometimes exhibits an open rustic arcade along a portion of the front or back, which will be found useful and agreeable both in sultry and cold broken weather. It is not uncommon for a cottage of this kind to have on the ground-floor two parlours, communicating by folding-doors, 14 feet by 12 each, and 10 feet in height; a kitchen and scullery, with a porch 7 feet by 5 feet 6 inches, opening to a staircase 17 feet 6 inches by 8 feet, with three rooms above. The gables are terminated with fineals and ornamental dressings to the doorways and windows, and handsome octagonal chimney-stacks. We offer a representation of a cottage in this elegant style in fig. 27.

Improvement is also shewn in the style of church-building, particularly in the northern part of the United Kingdom, where there was most room for it. Since the Reformation, churches have been built in Scotland with very little regard to elegance; and in the last century particularly, there flourished a style, the products of which are scarcely to be distinguished from barns and granaries. Within the last thirty years, very few ecclesiastical structures have been erected without an effort being made to unite some degree of taste with a regard for conveniency. A modest Gothic style has become very prevalent, which, though not always free from faults, is a surprising advance upon the homely edifices of the last century.

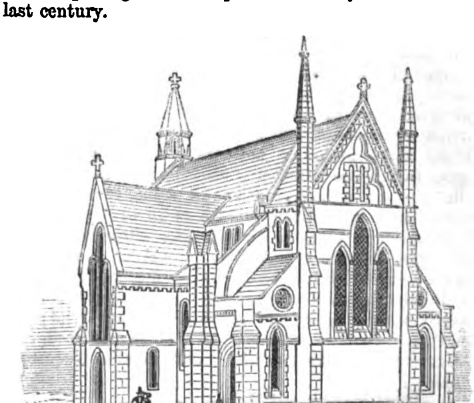

Fig. 28.

In fig. 28, a representation is given of one of these improved ecclesiastical structures, suitable for a rural scene, or any other situation in which economy of means requires to be consulted.

MODERN BRITISH ARCHITECTURE.

During the sixteenth century, as has been mentioned, an extraordinary effort was made in Italy to restore the purity of the ancient Roman or Romanised Grecian architecture; and in this attempt, Palladio was followed by the not less eminent Michael Angelo Buonarotti, who, at an advanced age, in 1546, undertook the continuation of the building of St Peter's at Rome, a work on which the greatest splendours of the Italian style are lavished. Into England, this revived taste for the Roman was introduced, at the beginning of the seventeenth century, by Inigo Jones, to whose contemptuous observations on the pointed style the term *Gothic* has been traced; and after his decease, the Roman, or, more properly, the Italianised Grecian, was perpetuated

on a scale still more extensive by Sir Christopher Wren. The edifices erected by this great master are characterised by the finest taste, and his spires in particular are models of elegance. The greatest work of Wren was St Paul's Cathedral in London, in which the Italian is seen in all its glory.

The eighteenth century was an era of decline in architectural taste. Every other style merged in that of a spiritless and often mean Græco-Italian, out of which the architects of the nineteenth century have apparently had a difficulty to emerge. Latterly, there has been a revival in England of a purer kind of Grecian, and also, as we have already said, of old English, and the Gothic or pointed style, and in most instances with good effect. It is only to be lamented that, by the manner in which state patronage is distributed in this branch of the fine arts, some of the largest and most expensive structures—Buckingham Palace and the National Gallery, for example—have been erected on the poorest conceptions of the Grecian style, and with a general effect far from pleasing. In Paris there now exist some modern structures after correct Grecian models, which cannot be too highly praised; we would, in particular, instance the building called the Madeleine, the Bourse, and the interior of the Church of St Genevieve. In England, besides a multitude of churches, the New Houses of Parliament present an instance of recurrence to the Gothic, being probably the largest edifice of that kind in the world.

Houses and Streets.

Till about the year 1820, the street-architecture of Britain was on a poor scale; the houses ranging evenly with each other, being plain stone or brick edifices of generally three stories in height, overtopped by a slanting and tasteless roof of slate or tile; in London, and some other places, the ugly tile roof was hid by a portion of the front wall carried upwards as a parapet. At the above period, a new era may be said to have begun in town-architecture, whereby the houses were built more in a bold continental style, in which the Græco-Italian was aimed at with more or less success; and latterly, this improved taste has altogether superseded the barren architecture prevalent during the reign of George III. According to this revived taste, the houses are now constructed of polished stone, or covered with a plaster to resemble that material; the doors and windows are enlarged and ornamented, the stories more spacious and lofty, and the roof is frequently

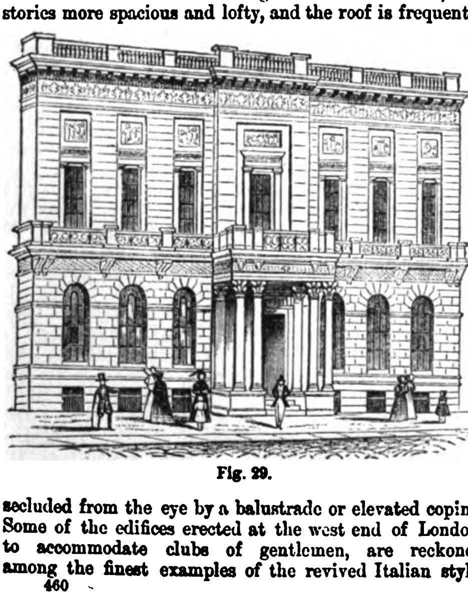

Fig. 29.

secluded from the eye by a balustrade or elevated coping. Some of the edifices erected at the west end of London, to accommodate clubs of gentlemen, are reckoned among the finest examples of the revived Italian style, and worthy of the best days of Palladio. The preceding cut (fig. 29) represents the front of the Oxford and Cambridge University Club-house, in Pall Mall, erected from a design of Mr Sydney Smirke, and distinguished for the richness of its cornice and entablature, as well as its generally imposing effect. The Carlton Club-house, in the same neighbourhood, is also by Mr Sydney Smirke, and is a very fine adaptation of the same style, upon a more magnificent scale.

The various changes effected in recent times in general street-architecture, are not more remarkable than those on the construction of shop-fronts, some of which now vie with the greatest efforts of the old Italian masters. A century ago, shop-fronts were little else than open booths, with an overhanging canopy. They afterwards were closed, and, as is well known, attempts were finally made to Grecianise them with pillars and pediments. The increasing rivalry and taste of shopkeepers, however, did not stop here; and in the present day, very extraordinary efforts are making to place shop-fronts among the works of classic architecture. The design, generally, is to supersede plain Grecian or Roman models by highly ornamental designs after the Italian style. The most favourable specimen we can present of this elaborate and splendid style of shop-frontage, is that observable at the corner of the Quadrant, Regent Street, London (fig. 30).

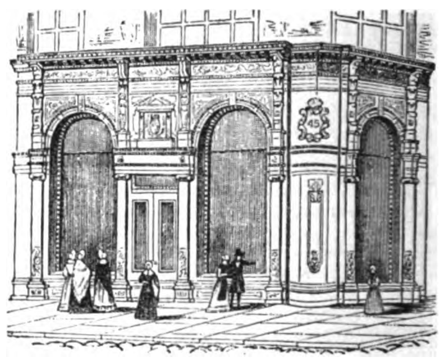

Fig. 30.

As an architectural composition, it possesses considerable merit, presenting, with the lightness of the plate-glass windows, the appearance of sufficient solidity and strength, and not looking as if likely to be crushed by the upper part of the edifice.

While recent edifices, with any pretensions to architectural effect, are thus, in themselves, superior to those of the last century, the fact that they are reproductions of classical or medieval designs, and that their merit is judged of by their correctness as copies, is certainly not satisfactory. It seems to indicate that architecture, as a fine art, is no longer among us a living art, as engineering is, which every day puts forth new developments under new exigencies, instead of seeking to revert to the past.

The constant recurrence to the past for the forms of ornamental architecture leads, besides, to endless incongruities. The ornaments, however beautiful in themselves, are often out of place, there being no real or apparent use for their being there. A pediment or portico, unless the termination of a real roof, and an integral part of the building, is a meaningless ornament, and is as inappropriate in Grecian as in any other style. The evil of a slavish adherence to classic models is seen in the case of windows. The invention of window-glass in the sixth century rendered a purely Greek building practically obsolete. The few windows of the ancients were placed high in the walls, and many chambers were lighted exclusively by torches. In some temples, the colonnade supporting the roof was open. Windows are now a grand feature in the building, for cupola-light is

not always attainable or always desirable; and windows, therefore, instead of being merely 'poked out,' should exhibit some distinctive characteristic of the order. The glass windows are not incongruous in themselves, being a modification of absolute necessity in the present age; but unluckily they are mere holes in the wall, with no more reference to the Grecian than to the Gothic style of architecture.

The Gothic, in like manner, becomes in our hands merely ridiculous. Baby-house towers and turrets—battlements where no battle can be waged—mock machicolations—niches in the walls for dolls instead of statues.

Amid this confusion of ideas and styles, Mr Fergusson (*Hand-book of Architecture*, London, 1855) points with satisfaction to the Crystal Palace at Sydenham, as at least one great building carried out wholly on a principle. 'No material is used in it which is not the best for its purpose; no constructive expedient employed, which is not absolutely essential; and it depends wholly for its effect on the arrangement of its parts and the display of its construction. . . . This, however, is only the second of a series. A third would probably as far surpass it, as it is beyond the first; and if the series were carried to a hundred, with more leisure and a higher aim, we might perhaps learn to despise many things we now so servilely copy, and might create a style surpassing anything that ever went before.' Such structures, however, from their ephemeral nature, are not suitable for the higher efforts of art. The iron-and-glass style, as it might be called, is chiefly valuable as a means of covering in a large space at a comparatively small cost. By the copious use of glass, and by taking skilful advantage of the rigidity of iron in its cast state, and of its tenacity as wrought iron (in forming *ties*), a firm and weather-tight fabric can be reared, with a smaller weight of materials than was ever dreamed of before.

MONUMENTAL COLUMNS.

The erection of triumphal or monumental columns was a favourite idea of the Romans. Augustus erected a column of white marble near the Temple of Saturn, in the Forum at Rome, as a centre whence the account of the miles began in the calculation of distances from the city. This celebrated column, which is still in existence,

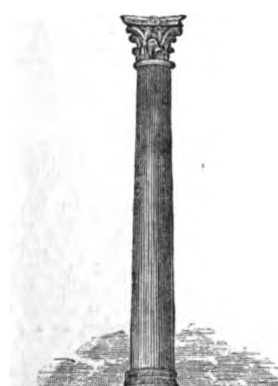

Fig. 31.—Pompey's Pillar.

is, however, not of great altitude. Among the principal triumphal columns of antiquity now remaining, is what is called the Column of Pompey, constructed of red granite, and situated on a rock, about a mile without the walls of Alexandria in Egypt. An inscription, now nearly effaced, seems to prove that it was erected in honour of the Emperor Diocletian by the then prefect of Egypt. The total height of this column is stated at 98 feet 9 inches, the shaft being 73 feet. The spectator can never be tired with admiring the beauty of its Corinthian capital, the length of the shaft, or the extraordinary simplicity of the pedestal.

The Trajan Column, which falls next to be mentioned, is one of the most celebrated monuments of antiquity. Its height, including the pedestal and statue, is 132 feet. This monumental column was erected in the centre of the Forum Trajani, and dedicated to the Emperor Trajan for his decisive victory over the Dacians, as is testified by the inscription on the pedestal. It is of the Doric order, and its shaft is constructed of thirty-four pieces of Greek marble, joined with cramps of bronze, and so curiously cemented as to appear but one entire stone. For elegance of proportion, beauty of style, and for simplicity and dexterity of sculpture, it is the finest in the world. The figures on the pedestal are master-pieces of Roman art. There are other columnar erections in Rome; one of which is the column of the Emperor Phocas, near the Temple of Concord; it is of Greek marble, fluted, and of the Corinthian order, 4 feet diameter, and 54 feet high, including the pedestal.

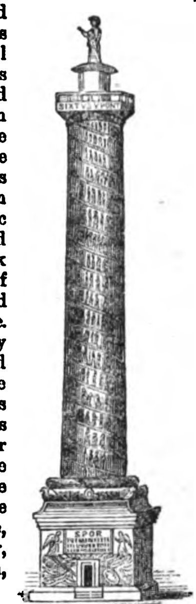

Fig. 32.—Trajan's Pillar.

The column which ornaments the British metropolis, better known as the Monument, was designed by Sir Christopher Wren, and erected by order of parliament, in memory of the burning of the city of London, anno 1666, in the very place where the fire began. This pillar was begun in 1671, and finished in 1677. It is of the Roman Doric order, fluted, 202 feet high from the ground, and 15 feet in diameter, of solid Portland stone, with a staircase in the middle, of black marble, containing 385 steps. The lowest part of the pedestal is 28 feet square, and its altitude 40 feet; the front being enriched with curious bass-reliefs. It has a balcony within thirty-two feet of the top, on which is placed a blazing urn of gilt brass.

The column in Phœnix Park, Dublin, differs from any other work of this description. It was erected in 1745. The pillar is formed of Portland stone, and is of the Corinthian order, fluted, and highly ornamented. The base and pedestal are 5 feet in height, the shaft and capital 20 feet, and the phœnix which surmounts the column 5 feet, so that the whole presents an object 30 feet high.

The Napoleon Column has justly been considered as the greatest ornament of the French capital. It stands in the Place Vendôme, and was erected to commemorate the successful result of Bonaparte's arms in the German campaign of 1805. Its total elevation is 135 feet, and the diameter of its shaft is 12 feet. It is in imitation of the Pillar of Trajan, and is built of stone, covered with bass-reliefs—representing the various victories of the French army—composed of the metal of 1200 pieces of cannon taken from the Russian and Austrian armies. The bronze employed in this monument was about 360,000 pounds-weight. The column is of the Doric order. The bass-reliefs of the pedestal represent the uniforms and weapons of the conquered legions. Above the pedestal are festoons of

oak, supported at the four angles by eagles, in bronze, each weighing 500 pounds. The bass-reliefs of the shaft pursue a spiral direction from the base to the capital, and display in chronological order the principal actions of the campaign, from the departure of the troops from Boulogne to the battle of Austerlitz. The figures are three feet high; their number is said to be 2000; and the length of the spiral band 840 feet. Above the capital is a gallery, which is approached by a winding staircase within, of 176 steps. The capital of the column is surmounted by an acroterium, upon which stands the statue of Napoleon, measuring 11 feet in height, and weighing 5012 pounds. The total expense of this sumptuous monument was 1,500,000 livres.

There are also several smaller columns, but of beautiful proportions, in various parts of England, in imitation of the above. A very common error is committed in the erection of monumental columns, by loading their summit with a clumsy mass of masonry, on which the statue is placed, and technically called an *acroterium*. The Melville monument at Edinburgh presents a notable instance of this kind of defect. If there must be an acroterium, it cannot be too modest in its proportions, or too little seen by the spectator.

THE PRACTICE OF ARCHITECTURE—CONSTRUCTION.

In erecting buildings, the first step to be taken is to select an appropriate site; after which, the designs have to be prepared, which is usually done at first in a sketchy manner, so as to be easily altered to suit the requirements of the party building. The sketches should comprise plans of all the stories, and elevations of all the parts, together with a perspective view, so that a more satisfactory idea may be formed of the actual appearance of the building when erected. The design being approved and determined upon, the 'working-drawings' have then to be made for the guidance of the contractors in estimating the cost of the erection, and of the workmen during its construction. The working-drawings are usually made to a large scale, and ought to represent, in due proportion, every portion of the work to be executed. Nothing should be left conjectural; every thing should be exhibited on the working-drawings, or described in the specification. The working-drawings consist of plans, sections, elevations, and detailed drawings. The plans, sections, and elevations are usually drawn to the same scale—never less than $\frac{1}{8}$th, and usually $\frac{1}{4}$th of an inch to one foot. The detailed drawings should be as much as possible drawn full size. The elevations are of various kinds—as *front*, *back*, or *end* elevation. They represent those portions of a building as they appear when viewed from points directly opposite—that is, without any perspective effect. The sections also vary in number, and are used to delineate the appearance of the structure as it would be if cut down from top to bottom in a direct line. As a plan shews the horizontal arrangement and connection of apartments, so sections do that of the vertical parts; as the height of the rooms, the position and arrangement of floors, roofs, partitions, &c. It is the architect's duty to prepare what is termed a *specification*. This requires to be very carefully drawn up, as it is the document which regulates the kinds and qualities of materials, and how they are to be used, and which defines exactly the duties of the builder. In large buildings, what are called *bills of quantities* are also drawn up, sometimes by the architect appointed to the works, sometimes by a disinterested surveyor. This document consists of a series of tables, in which the various measurements connected with the different departments are laid down; as the number of cubic feet of excavation required, the amount of brickwork, the surface of plastering, &c. This is handed to the party estimating, who affixes a price to each, and estimates accordingly. The architect usually receives, as an honorarium, a sum equal to 5 per cent. on the whole outlay. The construction of the building is intrusted to a builder, who is under the control and superintendence of the architect. All deviations from the specification are treated and allowed for as *extras* or *deductions;* these generally render the actual cost greater than the estimated, and are therefore to be avoided as much as possible, by thoroughly considering every point before the specification is drawn up. It is a good plan to insert a clause in the agreement, by which the builder executing the work agrees to undertake all extras at a certain rate.

In the construction of domestic buildings, certain points must be attended to, in order to attain stability, permanence, immunity from fire, and health. As to the questions of site and internal arrangements, so as to secure convenience and comfort, we refer the reader to the number on HOUSEHOLD HINTS, where suggestions of a practical character may be met with. Viewing it as a matter of some importance that a knowledge of what is requisite in house-building, to insure safety and health, should be more generally diffused than it apparently is now, we propose to devote the remainder of our present paper to a glance at the chief points—these being foundation, walls, floors, partitions, roofs, fire-proof construction. Our remarks will have a more particular reference to the styles of domestic construction usually adopted in England. They will, however, be easily applicable to other forms of structure.

As to the best method of preparing a site so as to secure a good and dry foundation, the reader will find some hints in our paper on THE HORSE, in the section on Stables. Fig. 33 shews the method of building the foundations; the wall rests on a series of *footings*, *b*, stability being secured by thus spreading out the bearings on which it rests. As a damp house will always be an unhealthy one, every care should be taken to prevent moisture gaining access to the walls. A proper treatment of the foundation will go far to effect this: filling in the trenches with concrete is a good plan.

Fig. 33.

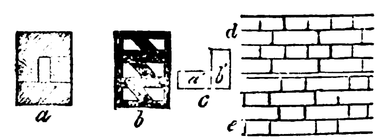

Fig. 34.

Another method, and one which, from its certainty, should be adopted where possible, is to raise the floor to such a height that the house must be approached by two steps at least.

Walls.—The important desideratum of dryness is attained also by the method of building *hollow walls*, now fast getting into use; which has the additional advantage of saving material. In fig. 34, we give various methods of building brick-walls hollow: *a* shews a section of a nine-inch wall, and *b* a nine-inch patent brick. In building brick-walls, there are two ways of setting the bricks, called old English and Flemish bond. When a brick is placed lengthways to the front, it is termed a *stretcher*, as *a'*; and a *header* when across the wall, as *b'* (*c*, fig. 34). In old English bond, which is the safest, a row of headers and a row of stretchers alternate, as *d*, fig. 34; in Flemish, a header and a stretcher alternate in the same row, as *e*, fig. 34. To secure what is called *bond* in brick-walls—that is, a thorough cohesion between the various parts—strips of sheet-iron, covered with tar, are built in as the work progresses. Wood bonding should seldom be used, because of its liability to decay. In carrying up brick-walls, care should be taken to see that the workmen do not build one part at a quicker rate than another: the whole should be carried up evenly, which will secure uniformity of settlement, and prevent cracking. When finished, the outer joints should be *pointed*—that is, well filled up with mortar; and as the work proceeds,

the brickwork should be *grouted*, or run in with liquid mortar. All openings for doors, windows, and fireplaces should be arched over. Where timber is used for lintels, it should be of the best description: English oak, or Baltic timber, is the best adapted for the purpose. All lintels should have as little bearing on the walls as possible, consistent with stability. Timber in walls is bad on account of its liability to decay. Stone-walls are usually constructed solid, but they may be made hollow with advantage, although this will be more difficult of execution than in brick. Where all the stones are squared and worked on the face, the wall is termed *ashlar;* where they are of irregular size, it is termed *rubble*.

Floors consist of three varieties: composite, stone or brick, and wood. For cottages, the ground-floors may be made very cheaply and efficiently, thus: lay evenly a concrete of broken brick and tar; upon this, spread a mixture composed of lime ashes and sand; when dry, if rubbed over with linseed-oil, it will have the appearance of stone. Stone-flags are generally used for the formation of kitchen and lobby floors. For the former, hollow bricks will be cheaper; and for the latter, encaustic tiles more elegant. Timber floors are generally constructed in one of two ways. The two methods are delineated in fig. 35, where A shews a *single*

A B

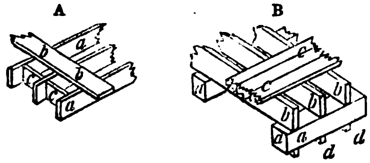

Fig. 35.

flooring, and B a *double*. In the former, the beams or joists, *a*, rest upon the walls at either end, and upon them the flooring-deals, *b*, *b*, are laid. The distance between the joists should not exceed 12 inches. Strength is obtained by having the joists thin and deep. For a distance of 12 feet from wall to wall, 8 inches deep by 3 thick will be found ample. When the bearing exceeds this, or even 8 feet, stays of thin pieces of wood, the same depth as the joists, may be inserted between the joists in a line, as at *c*, called *bridging*, which makes the floor firm and steady. A double floor consists of a series of *binding-joists*, *a*, *a*, resting on the wall, the distance between them being usually 6 feet; on these the *bridging-joists*, *b*, *b*, are laid, which, again, support the flooring-planks, *c*, *c*. The distance between the bridging-joists, *b*, *b*, is from 12 to 18 or 20 inches. For upper floors, the ceiling-joists of the room below are fixed on the under part of the binding-joists, *a*, *a*, as at *d*, *d*. A third kind of floor is sometimes employed in cases where the distance from wall to wall is great: it is termed a *framed floor*, and is much more complicated, the binding-joists resting upon heavy beams, termed *girders*, which rest on the walls. The introduction of iron beams, where extent of span is required, is now common, and is a very great improvement upon the old system. The use of iron beams is also now very common in the construction of fire-proof buildings, iron beams being placed at intervals of from 8 to 10 feet apart, in order to receive the brick arches, of which the fire-proof floors are composed. The passage of sound is prevented by *deafening*, which is effected by nailing strips of wood inside the joists, a few inches below the upper edge, and along the whole length; on these, pieces of board or lath are laid across, forming a species of floor, on which mortar is laid. This is called *pugging*, or counter-ceiling. In placing the ground-floors, care should be taken to have a due supply of air underneath the timbers; this will prevent, in great measure, the ravages of the dry-rot. In all cases, if possible, the ends of the joists should not be built in with the walls, but should rest in special apertures made therein for them. In some cases, iron shoes are built into the walls, in which the ends of the beams are placed. The ground-floor joists should rest on short piers carried up from the foundation—the object in all these cases being to have a free circulation of air around the timber, and to keep it as free as possible from damp. Where openings occur in the line of floor-timbers—as at fireplaces, staircases, &c.—an expedient known as a *trimmer* is used, exemplified in fig. 36. The wall opposite these openings being no longer

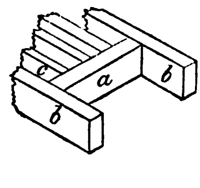

Fig. 36.

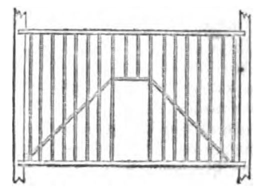

Fig. 37.

available as a bearing for the joists, the ends are supported by the *trimming-joist*, *a*, which is framed into the two joists, *b*, *b*. These joists are termed the carriage-beams, and have to be stronger than the ordinary joists, in proportion to the weight which the trimmer has to support.

Partitions require to be carefully attended to. The whole of the framework should be so arranged as to discharge all the weight upon the points of support, and relieve the floors, &c., below of all undue strain. In fig. 37, we give an illustration of a partition with a door in the centre.

Stair-steps, as generally arranged, are of two kinds—*flyers* and *winders*. In the former, all the steps are parallel, and lead from one story to another in two or more flights; resting-places being made at intervals by platforms, which serve also to change the direction. In the latter, the steps are narrower at one end than the other, and wind continually round a central shaft or cylinder. Parallel shaped steps are sometimes used in conjunction with the tapered ones. Staircases are generally more convenient when placed in the centre of the building; in this case, they are lighted by means of a sky-light above, which affords at the same time facilities for ventilation.

A wooden stair-step is composed of a *tread* and a *riser;* the tread is the flat surface on which the foot is placed, the riser is the vertical portion beneath the tread. The flight of steps are usually supported on stout *carriages*—lengths of timber in a raking position. The risers should be as near 6 inches high, and the tread 12 inches wide, as conveniency of space and situation will allow. The length of steps in private buildings varies from 2½ to 3½ feet.

Roofs, as constructed for modern private buildings, are an arrangement of timbers so disposed as to distribute the weight equally, and ultimately to deliver it on the walls or pillars intended for its support, avoiding all lateral strains calculated to thrust the walls out. In old buildings, so thick were the walls, and capable of resisting any outward thrust, that the *tie-beam* was unknown; so thin, however, are modern walls, that this avoiding of lateral thrust is specially to be attended to. The simplest form of roof is a *lean-to*, used where the back wall is higher than the other; a piece of timber is built in longitudinally along the top of the walls; the rafters are nailed to these at top and bottom, and the roof boarding on these. In a house with gable-ends, the simplest form of roof is a *ridge-pole*, or timber stretching from end to end of the house, and built in at the apex of the gable. The ends of the rafters abut against this at one end, and are nailed to *wall-plates*, formed of timber laid

on the walls. Where the building is of large dimensions, what are called *trusses* are used. These are placed at certain distances apart—say ten feet—and the rafters, &c., supported by them. Fig. 38 shews a form of truss:

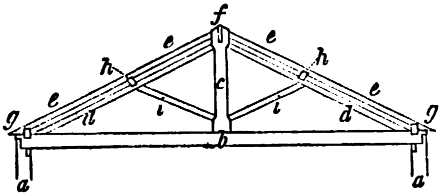

Fig. 38.

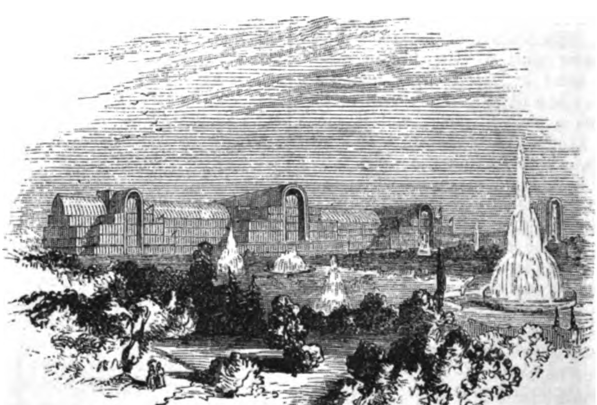
a, *a*, the walls; *b*, the tie-beam; *c*, the kingpost; *d*, *d*, the principal rafters, abutting at one end on the upper part of the kingpost, and at the lower on the end of the tie-beam. The ridge-pole, *f*, is let into the head of the kingpost, and stretches from truss to truss. The *common rafters*, *e*, *e*, are fastened to the ridge-pole at one end, and to the *poll-plate*, *g*, at the other. An intermediate support is also provided in the *purlins*, *h*, *h*, which are timbers let into the principal rafters, and stretching from truss to truss parallel to the ridge-pole; *i*, *i*, struts or stays.

Doors, Windows.—The width of entrance-doors varies from 2 feet 6 inches to 3 feet 8 inches; the height, 6 feet 6 inches, more generally 6 feet 8 inches. Internal doors are generally 2 feet 8 inches wide; closet-doors, 2 or 4 inches narrower. Internal doors are generally made with four panels. The moulding round the door-case is termed the *architrave*. Common doors, formed of a series of boards grooved together, and having cross strips nailed at the back, at top, bottom, and centre, are called *ledged*. *Windows* are of uniform breadth in a house; but those of each story differ in height from those above or below them. The height of a principal window should be $2\frac{1}{4}$ times the width; a second floor, $1\frac{3}{4}$ times; the third story, $1\frac{1}{2}$. For information on ventilation, construction of fireplaces, see number on HEATING.

Fire-proof Construction.—It has been truly remarked, that if our builders had been endeavouring to establish one mode of construction better than another for the facilitating of fires, they could scarcely have devised a better than the one now in such general use. The great point seems to be to use as much timber as possible, and to place it so that it will serve to convey the fire quickly from one place to another; hollow floors, ceilings, partitions, hollow spaces behind skirtings, all serve as chimneys—and chimneys themselves of the most inflammable materials; staircases fitted so as to burn with the greatest possible rapidity, beams thrust into chimney-flues, hearthstones resting on timber; the grossest carelessness everywhere observable. This is no exaggeration, but a simple statement of facts, and the wonder is not that so many, but that so few fires happen. If a system of solid, rather than honeycomb construction were adopted, we should have more safety from the ravages of fire. The construction of Scotch buildings contrasts favourably with the English mode. This solid system can be as cheaply obtained as the other, which is deprecated so much. By the use of hollow bricks, partitions can be made absolutely fire-proof; and by the adoption of the Parisian plan of forming floors and ceilings, fire, if breaking out in one apartment, can be confined thereto. The plan here alluded to may be briefly described as a system of forcing mortar between the joists of the floors with considerable pressure, so that the timber is, as it were, imbedded in a non-conducting material, which requires to be made almost red-hot before the timber can be touched. With our present system of plastering, a very moderate degree of heat serves to make the plaster peel off, exposing at once the wood, and opening up the series of hollow spaces before alluded to, which quicken the action of the fire. Wooden staircases, by the system of underlathing and mortaring, can also be made fire-proof. Space will not allow us to go further into this interesting subject.

Varieties of Domestic Structures.—Throughout England, the houses are generally constructed so that each has a separate entrance, or is self-contained, as it is called. In Scotland, town-houses are generally arranged in 'flats'—the first story only being self-contained, and the suits of rooms on the several stories above forming separate dwellings, with entrances from a common-stair. This plan of constructing houses is well adapted for the labouring-classes, as the ground-rent and other expenses are distributed over a greater number of tenants. For various hints of importance to building capitalists on this subject, see a pamphlet by Mr William Chambers. This work contains also some useful remarks on dwelling-places for the labouring-classes, a subject which occupies so much at present the attention of philanthropists.



Crystal Palace—Sydenham.

WARMING, VENTILATION, LIGHTING.

WARMING.

THE average temperature of the human body * is from 98° to 100°; and whether the individual be exposed to a tropical or to an arctic climate, his blood never rises above or falls below the medium more than one or two degrees, whatever his feelings of heat or cold may be. It seems as if this amount of heat, and no other, were consistent with the existence of warm-blooded animals; for if by any means the temperature of an animal's body is reduced below the above limit, its vital action declines, and soon comes to a stand. In like manner, when heated seven or eight degrees above its usual warmth, the vitality is destroyed.

The temperature thus necessary for the life of the body, is maintained by the action of that life itself. Objects surrounding the body being in almost all cases colder than it, are constantly stealing part of its warmth; but within the system there is an incessant process of combustion going on, producing fresh heat, exactly as the fire in a grate does. When the heat thus generated is not dissipated fast enough, so that the body tends to become warmer than the due degree, the accumulation finds vent in perspiration, the evaporation of which carries off the excess (see NATURAL PHILOSOPHY). In general, however, the tendency is the other way; the heat of the body, if allowed freely to escape, would be dissipated faster than it is produced; and hence arises the necessity of clothing, houses, and other means of retarding its escape. The lower animals are in general provided by nature with coverings for this purpose, according to the requirements of the climate in which they live. Man is left to the exercise of his inventive faculties to provide clothing and shelter for himself. In the lower animals, too, the heat-producing function is more active than in man. At least, this is true of civilised man; for there can be no doubt that the naked and painted savages that inhabited these islands 2000 years ago had a power of resisting cold unknown to us their descendants. In this respect, at least, the race has degenerated. At the present day, in fact, the people that inhabit Tierra del Fuego and the west coast of Patagonia, though living in a climate in which there is hardly a day without rain, snow, or sleet, and not a month without frost, have no covering except a scrap of hide tied to the waist. Even in civilised communities, those that lead a life of activity in the open air require far less protection from the cold than those that live indoors. There is, besides, the greatest difference in this respect between individuals, though placed in exactly similar circumstances—a difference intimately connected with the soundness of the digestion and other nutritive processes. From not recognising this constitutional difference, serious errors are committed. The cold-blooded are accused by the more hardy—and are apt to accuse themselves—of effeminacy, as if they were merely shrinking from a disagreeable sensation. But the truth is, that the sensation of cold on the surface, which merely makes the skin of the strong man smart, and for the rest only stimulates the system to produce more heat than ever, quickly lowers the temperature of the less vigorous to a greater depth, and deprives the vital powers of the ability to react.

* The average temperature of the other mammalia is almost the same as in man; that of birds is 106°; reptiles, fishes, insects, &c., differ little in warmth from the air or water in which they live.

It is well, no doubt, for even the weak to encounter cold, provided they keep in motion. But to encounter cold and overcome it, is a very different thing from passively suffering cold. To allow the body to continue depressed in temperature beyond the natural state, instead of hardening, infallibly weakens its vitality, and sows the seeds of disease. And that this error is committed on a vast scale, in Britain more especially, is apparent enough. The feelings of buoyancy which most persons in tolerable health experience during a clear frosty day, have led to a general belief in the peculiar healthiness of cold weather. But the statistics of death and disease tell a different tale. The reports of the registrar-general shew that, exactly as the thermometer sinks, the rate of mortality rises, and certain diseases of the most fatal kind become more prevalent; the vitality, in short, of the community decreases as the warmth of the atmosphere decreases. Whatever comfort, then, or temporary benefit the more vigorous individuals may derive from cold, it is clear that the community at large suffer from it—suffer seriously, both in comfort and health. We believe it to be an established fact, that the means generally taken to arrest the waste of heat from our bodies, or to supplement it, are, for the majority of men and women, insufficient, or injudiciously managed. This is a matter of literally 'vital' moment to one and all. The economy of heat is a primary element in the art of living in health and comfort; and no 'knowledge of common things' that we can think of, can surpass in importance a right understanding of the principles and facts on which that art rests.

We have as yet spoken of arresting the dissipation of the natural heat by clothing and shelter; and this, among some nations, is made to suffice. Where fuel is scarce, the resource against the cold of winter is thick clothing indoors as well as out. This is said to be the regular practice in China; and even in the south of Europe, fires are dispensed with in weather when we should think them absolutely necessary, and additional wrappings are considered as appropriate while sitting in the house, as in the open air. But wherever fuel can be had, it is always preferred to wear within doors much the same clothing in winter as in summer, and to keep the apartments nearly at summer temperature by artificial heat. It is this special branch of the subject, namely, the artificial warming of apartments, that we are at present to consider; that of Clothing will be treated in a subsequent number (see also PRESERVATION OF HEALTH).

In order to regulate temperature, we must first know the nature of heat—how it is produced, and what laws it follows. This forms a branch of the science of Physics, and has been briefly treated in NATURAL PHILOSOPHY. But for the better understanding of the present subject, it may be well to say something more here of

Combustion,

Which is the chief source of artificial heat. Combustion consists in the rapid union of the oxygen of the air with some substance for which it has a strong chemical attraction, and which is called a combustible or fuel. All chemical combination produces heat; but it is only called combustion when the heat is so intense as to produce light. The cheapest combustibles or fuels are coal, wood, peat, coke, and charcoal, which consist chiefly of two simple bodies or elements, carbon and hydrogen (see CHEMISTRY). Before oxygen will unite with the combustible, the latter must be heated to a high pitch; the combustion once begun in one part of the fuel, is then

sufficient to keep the rest at the combining temperature, provided the heat is not too rapidly dissipated. One piece of fuel will seldom keep alight alone; a number of pieces require to be burned together, in order to keep one another warm. To blow cold air rashly into a weak fire, puts it out, by suddenly cooling the coal below the combining point. A cold poker held near the flame of a candle will extinguish it; and a fire, on the other hand, burns much better when surrounded by bricks, than by metal. The bricks act like clothing, and keep in the heat of the coals; the iron being a good conductor, runs away with the heat as fast as it is generated, and passes it into the wall, making the coals that touch it dull and black.

Products of Combustion.—The carbon of the fuel unites with $2\frac{2}{3}$ times its weight of oxygen, forming carbonic acid gas, and the hydrogen with 8 times its weight, forming water in the state of vapour or steam. For the complete combustion of a pound of coals of average quality, about 230 cubic feet of air are required; of which some 46 feet are oxygen, and the rest nitrogen, which takes no part in the combustion. This nitrogen mingles with the carbonic acid and vapour before mentioned, and the whole ascend from the fire in the form of a heated gaseous current, which, when the combustion is complete, is colourless as common air. Were the fuel composed of carbon and hydrogen alone, these would be the only products of perfect combustion; *ashes* arise from earthy incombustible substances in the fuel, which lessen its value. If the fuel contain water, the water is driven off in steam, and carries away a great deal of the heat of the fire in a latent form. From this cause, green wood gives little heat; and coals when wetted give less than the same quantity burnt dry.

The really valuable product of combustion is the heat evolved. There are various ways of measuring its amount—as by the quantity of ice it melts, or the number of degrees to which it heats a certain quantity of water. Thus, it is found that the burning of one pound of good coal melts 90 pounds of ice; of coke, 84 pounds; of wood, 32 pounds; of charcoal of wood, 95 pounds; of peat, 19 pounds. In speaking of the heating effects of combustion, it is specially necessary to bear in mind the different capacities of bodies for heat, or their *specific heat.* Water, for instance, has great capacity for heat, or is very difficult to warm. The same amount of heat that raises the temperature of a cubic foot of water 1°, will heat 2850 cubic feet of air to the same extent.

The combustion of fuel is seldom perfect, except in the case of coke, wood-charcoal, and anthracite coal, which are composed of carbon without hydrogen. Common coal consists partly of carbon, and partly of bitumen or pitch. The bitumen also contains carbon, but in combination with the volatile gas, hydrogen; and when heated to a certain degree, it rises or distils off in vapour. If the heat is only about 600°, this vapour is thick and black, constituting *smoke*, and as it cools, it deposits *soot*, which is carbon in fine powder. A greater heat makes the carbon and hydrogen take another arrangement, and become carburetted hydrogen gas—common coal-gas—which is transparent like air, and does not deposit carbon when cold. It is this highly heated gas, combining with the oxygen of the atmosphere, that constitutes *flame.* The pitchy vapour rising from burning fuel is not hot enough to combine with oxygen, unless it come in contact with flame or hot coals. It thus appears that fuel which burns with flame has always more or less hydrogen in it; coke and charcoal, from which the gaseous part has been driven off, burn without flame.

We now proceed to consider the application of the heat thus generated to the warming of dwellings, keeping in view rather the illustration of the general principles that should guide every such application, than entering into constructive details of apparatus.

The great aim, it may be premised, in all plans of warming is, as it is expressed by Dr Arnott, '*to obtain everywhere on earth, at will, the temperature most congenial to the human constitution, and air as pure as blows on a hill-top.*' The obtaining of the desired temperature would be comparatively easy by itself; the difficulty lies in combining warmth with pure air. The various plans hitherto tried may be classed under the four heads of—The Open Fire, Stoves, Gas, Steam and Hot Water.

THE OPEN FIRE.

The first application of artificial warmth consisted, most likely, in lighting a fire of dried sticks and leaves in a grove, a cave, or other natural shelter. When tents or wigwams came to be erected, the fire would be lighted on the middle of the floor, with perhaps a hole in the roof for the smoke to escape by. This primitive arrangement may still be seen in some of the cabins of Ireland and the Scottish Highlands. The Romans warmed their apartments chiefly by portable stoves or chafing-dishes, without any regular exit for the smoke and fumes; and a brasier of charcoal is still the chief means of lighting sitting-rooms in Spain and Italy, which are in general without chimneys. As late as the fourteenth century, the hearth in Britain continued to be in the middle of the apartment, and the smoke escaped by an opening in the roof, called the louvre (Fr. *l'ouvert*). At last, the fire was placed at the side, in a sort of apartment formed by two projections, within which were placed seats where the warmth might be enjoyed. This recess came gradually to be built in the thickness of the wall, and was thus transformed into the modern chimney.

It is scarcely necessary to remark, that the mode of heating apartments now most prevalent in Britain is by a fire of coal placed in a grate, having a chimney above, through which the vaporised products of the fuel are carried off. Of one class of results from this mode, there can be no doubt. The fire glowing in its appropriate receptacle has an air of cheerfulness and comfort, causing the domestic group to cluster around it with that feeling of satisfaction which makes an Englishman regard his fireside as amongst the most precious things connected with his existence. But while the common open fire is almost an object of worship amongst us, on account of its pleasant look and power of concentrating the whole family in one social circle, it is not unattended with certain drawbacks and disadvantages: the greatest of these is the uneconomical use which it makes of fuel. About one-half of the heat produced by a common fire ascends with the smoke; the black part of the smoke itself being an unconsumed part of the fuel. Finally, about a fourth of the heat which is radiated into the apartment is, in ordinary circumstances, carried into the chimney between the fire and the mantelpiece, and thus lost. It is calculated by Dr Arnott, that only about one-eighth part of the heat-producing power of the fuel used in common fires is realised, all the rest being dissipated into the surrounding atmosphere. It is also unquestionable that often a common fire is found to give a partial kind of warmth, heating the side of our persons next to it, but leaving the rest cold; and that it produces draughts into our rooms which are anything but safe or agreeable. Notwithstanding these and other acknowledged evils, the open fire continues to hold its place, partly perhaps from prejudice, partly from real points of superiority over other methods as yet practised; and the object of late has been, not so much to do it away, as to improve it.

Grates.—One improvement consists in diminishing the quantity of metal in immediate contact with the fuel, and forming the back and sides of the grate of fire-bricks. For the reason given above, this renders the combustion more complete and the fire far hotter; and therefore the same quantity of fuel not only produces

more heat, but throws a greater proportion of that heat out into the room, and less up the flue and through the wall, than when it is surrounded by a mass of iron; for radiation depends more upon the intensity of heat than upon its quantity.

Another point deserving attention is the shape given to the chimney-mouth, or recess above the grate. When the sides are square with the back, none of the heat falling on them is given out again into the room. With a view, therefore, to throw out the heat better, the sides, or *covings*, as they are called, are inclined to the back at an angle of about 130°; and sometimes they are made curved and of polished metal, in order that they may reflect the heat without absorbing it. It is questionable if simple brick slabs, placed at the proper angle, do not throw out more heat than the most splendid polished metal plates. For though the bricks do not reflect the rays of the fire, they become heated themselves, and then radiate their heat into the room. Plates of rough metal absorb the heat that falls upon them as the brick does; but being good conductors, the heat passes through them into the wall, and thus they never become hot enough to radiate sensibly.

Much also depends upon the shape of the fire-box, or grate itself. To see the importance of this, it is necessary to attend carefully to the exact way in which an open fire heats a room. It does so almost entirely by the rays of heat that it throws out; and these rays do not warm the air directly; they pass through it like light through glass, just as the hottest rays of the sun pass through the upper atmosphere, leaving it cold enough to freeze mercury. It is only when the rays of the fire fall on the floor, furniture, and walls of the room, that they give out their heat; and it is by coming in contact with these solid heated bodies that the air is gradually warmed. We may thus see the necessity of having a fire lighted and burning brightly for a considerable time before the hour when the apartment is expected to be comfortable.

The law that radiant heat neither affects nor is affected by the surrounding air, also explains the fact that an apartment may feel very cold, though the air in it be at high summer heat. A church or other massive stone building in frosty weather may be filled with heated air, and yet retain its chilling effect for many hours. The warmth of the living body is lost in two ways: the film of colder air that touches it receives part of its heat by conduction, and rising up makes room for another film to do the same; a moderately heated body in cooling, is robbed of about half its heat in this way. The other half is given off in rays, which pass through the air and impinge upon the objects around. These objects are radiating back heat in return; but their temperature being low, the return is small, and the warmer body is colder by the difference. Hence we are chilled by a cold wall or a cold window without touching it, and though the air between us and it may be at 70°.—To return to the shape of the grate.

The chief object is to present as large a surface as possible of glowing fire to the front. With this view, the grate is made long and deep, in proportion to its width from front to back. This principle, however, is carried too far in many grates. The stratum of fuel is too thin (see p. 66) to burn perfectly, especially in the narrow angles at the sides, where the coals seldom get to a red heat, and are only warm enough to distil away in smoke. Such fires are constantly going out, and are further from being economical than a square box.

The practice recently come into vogue of placing grates almost on a level with the floor, has been demonstrated by Dr Arnott to be a complete mistake. It is as the winter, contrasted with the summer sun.

The chimney-throat, instead of a gulf drawing in a constant wide current of the warm air of the room, and causing draughts from windows and doors towards the fireplace, should just be sufficient to admit the burnt gases and smoke that come directly from the fire, and no more. This is the object of the movable plate in what are called *register-grates*.

It would be endless to attempt to enumerate the various forms of grate constructed, with more or less success, on the above principles. We shall content ourselves with a notice of the recent invention of Dr Arnott, to whom the subject of warming apartments is more indebted than to any individual since the days of Count Rumford. It comes nearer to the idea of perfection in an open fireplace than any previous contrivance. Its peculiar advantages will be understood from the following description:

Arnott's Smokeless Grate.—ab, ef, represent the front bars of a grate in a chimney of the usual construction, *rswu*.

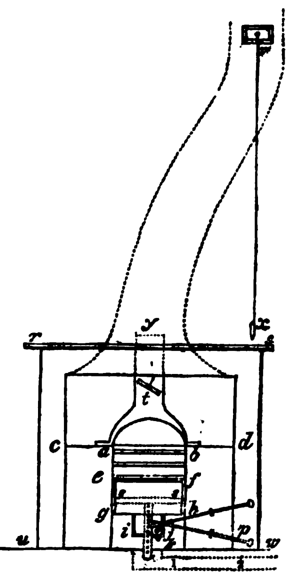


Fig. 1.

The grate has no bottom, and below it is an iron box, open only at top, into which the charge of coal for the day—from twenty to thirty pounds—is put. Any kind of coke or coal may be used. To light the fire, the usual quantity of wood is laid on the surface of the fresh coal at *ef*, and a thickness of three or four inches of cinders or coked coal, left from the fire of the preceding day, is laid over all. 'The wood being then lighted, very rapidly ignites the cinder above, and at the same time the pitchy vapour from the fresh coal below, rises through the wood-flame and cinders, and becomes heated sufficiently itself to become flame, and so to augment the blaze. When the cinder is once fairly ignited, all the bitumen rising through it afterwards burns, and the fire remains smokeless.'

As there is no supply of air but through the bars in front, the box being close underneath, the fire must be gradually raised up as the combustion goes on; and this is effected by having a false bottom, *ss*, in the box, which can be moved like a piston by means of a rod. The rod has notches in it, and, by means of the poker used as a lever, can be raised up and then retained at any height by a ratchet-catch. When the piston comes level with the bottom bar of the grate, the coals may be replenished while the fire is burning, by pushing in a flat shovel over the piston, so as to form a temporary bottom to the grate, and support the fire, while the piston is allowed to descend to the bottom. The shovel is then raised up a little in front, or a part of the upper edge of the box is made to fold down, and fresh coals are shot into the box;

on which the shovel is withdrawn, and the combustion goes on as before.

'A remarkable and very valuable quality of this fire is, its tenacity of life, so to speak, or its little tendency to be extinguished.' Even after it sinks below the level of the box, it does not go out, but continues to smoulder slowly for a whole day or night, and is ready to burn up actively when the piston is raised.

'In certain cases, as during long nights, it may be desirable to insure the maintenance of the slow combustion with rather more activity, and for this purpose there is a slide in a small door at the bottom of the coal-box, by which a graduated admission of air may be allowed. That door itself is opened quite before lighting the fire, to allow of the removal of the coal-dust or ash which, during the preceding day, has fallen down past the edge of the piston.'

Another peculiarity of the Arnott grate is the means taken to diminish the proportion of the heat usually carried up the chimney. Of the thick column of smoke that issues from a common chimney-can, only a small fraction is true smoke or burned air; the rest consists of the warmest air of the room, which becomes mixed with the true smoke in the large space usually left between the top of the fire and the throat of the chimney. 'The whole of the air so contaminated, and which may be in volume twenty, fifty, or even a hundred times greater than that of the true smoke, or burned air, is then all called smoke, and must all be allowed to ascend away from the room that none of the true smoke may remain. It is evident, then, that if a cover or hood of metal be placed over a fire, as represented by the letters *yab* in the diagram—or if, which is better, the space over the fire be equally contracted by brickwork, so as to prevent the diffusion of the true smoke, or the entrance of pure air from around to mix with it, except just what is necessary to burn the inflammable gases which rise with the true smoke—there will be a great economy. This is done in the new fireplace, with a saving of from one-third to one-half of the fuel required to maintain a desired temperature. In a room, the three dimensions of which are fifteen feet, thirteen feet and a half, and twelve feet, with two large windows, the coal burned to maintain a temperature of 65° in cold winter days has been eighteen pounds for nineteen hours, or less than a pound per hour.'

The hood is furnished with a throttle-valve or damper, *t*, having an external index, shewing its position, so as to give complete control over the current. The provision made for ventilation in this fireplace will be considered in another part of the paper.*

Even in this, perhaps the most economical form of open fire yet contrived, there is still great waste of the heat actually produced by the combustion. To say nothing of what passes by conduction from the fire itself into the wall, and is mostly lost; the quantity carried off in combination with the hot gases, though no more air is allowed to enter than is necessary for complete combustion, is still great. It deserves being noticed, that the proportion thus carried off is greatest in the case of fuel that burns with flame. Experiment shews that a fire of wood radiates one-quarter of its heat, the rest flying up; while the radiation from wood-charcoal is one-half of the whole heat produced. Every one has felt that a *blazing* fire has far less warming effect than a glowing one. Not that flame has not intense heat in it—more intense even than a glowing fire; but it gives it out only by contact, and not by radiation. It thus appears that any mode of heating that depends upon direct radiation, as the open fireplace chiefly does, necessarily involves great waste of fuel. This can be avoided only by applying the heat on a different principle, which consists in first making the fire heat certain apparatus with considerable surface, which then, by radiation and contact with the air of the apartment, diffuses its heat throughout it. This is the principle of the other methods of warming, which we now proceed to describe. The consideration of methods that combine the two principles, will come most conveniently last.

* Grates of this construction are manufactured by F. Edwards, Son, & Co., 42 Poland Street, Oxford Street, London, at from £2, 10s. to £7, 10s., according to the size of the apartment. With architectural decorations, in various styles, they cost £10–£30.

WARMING BY STOVES.

A *close stove* is simply an enclosure of metal, brick, or earthenware, which is heated by burning a fire within it, and then gives out its heat to the air by contact, and to surrounding objects by radiation. The simplest, and, so far as mere temperature is concerned, the most effective and economical of all warming arrangements, is what is called the Dutch stove; which is simply a hollow cylinder or other form of iron standing on the floor, close at top, and having bars near the bottom on which the fire rests. The door by which the coals are put in being kept shut, the air for combustion enters below the grate; and a pipe, issuing from near the top, carries the smoke into a flue in the wall. If this pipe is made long enough, by giving it, if necessary, one or more bends, the heated gases from the fire may be made to give out nearly all their heat into the metal before they enter the wall; and thus the whole heat of the combustion remains in the room.

The great objection to this form of stove is, that the metal is apt to become overheated, which not only gives rise to accidents, but has a hurtful effect upon the air. The exact nature of the change that highly heated metal produces upon air is not very well understood. It cannot be said to burn it, in the proper sense of the word, for none of its oxygen is abstracted, but it gives it a peculiar odour, which is both unpleasant and unwholesome. This is thought to arise in some measure at least from the hot iron burning the particles of dust that light on it, which particles consist of organic matter, such as wool, wood, &c.

Part at least of the unwholesomeness of air so heated arises from its excessive dryness; it parches and withers everything it touches, like the African simoom. It must not, however, be supposed that this is peculiar to air heated by contact with metal; *air suddenly heated is always unwholesomely dry.* This is an important point in regard to the subject of warming, and requires consideration. The relation of vapour to the air is fully explained in METEOROLOGY, which the reader is recommended to consult in connection with this subject. It may be stated shortly here, that a cubic foot of air, say at 32°, can contain a certain quantity of moisture and no more; but if heated to 80°, it is capable of containing *five* times as much, and has thus become *thirsty*, and drinks up moisture from everything that contains any. The heating of air, therefore, does not dry it, in the sense of taking moisture from it, it only renders it greedier of more; and this is equally true whether it is heated by a stove or an open fire. The chief difference is, that in the latter case the warming is more gradual, and no part of the air becomes very highly heated; while the air that touches a metal plate near redness is all at once rendered intensely thirsty, and before its fierceness is tempered by thoroughly mixing with the rest of the atmosphere of the room, must be highly pernicious. But whenever the temperature within doors is much higher than without, the air is in a too thirsty state, and parches the skin and lungs, unless means be taken to supply the necessary moisture. An evaporating pan or other contrivance is an essential part of warming apparatus; it is specially necessary to attend to this during east winds, which are generally too dry even at their natural temperature.

All improvements on this simple and rude form of stove aim at avoiding a high heat in the warming surface,

and this chiefly by lining the fire-box with brick, and enclosing it in several casings, so as to enlarge the heated surface. A general notion of these contrivances may be got from the annexed cut (fig. 2), representing the kind of stove called a *cockle*. The fire is burned in a small furnace within the inner case, and the air is warmed by circulating between the inner and outer cases. When placed in the apartment or hall to be warmed, the outer casing has perforations about the top for the issue of the warm air. For heating churches and similar buildings, the stove is placed in a separate furnace-room, and the warm air is conveyed to the different parts of the building in pipes or flues, while fresh air is drawn to the stove through a channel or culvert leading from outside the building to the openings in the outer casing, where the arrows are seen entering.

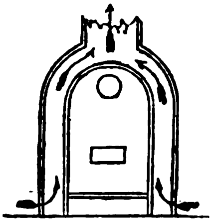

Fig. 2.

The stove invented by Dr Arnott is upon the same principle of an extensive and moderately warm heating surface. Under a sense of professional honour, Dr Arnott did not take out a patent for his stove. It was therefore made by many furnishing ironmongers in the metropolis and elsewhere, some of whom took out patents for what they considered as improvements upon it. No fewer than twelve patents were taken out in one year for modifications of this stove, *all of which Dr Arnott considered to be upon false principles*. The consequence has been, that many Arnott stoves, which had been introduced into houses, have been given up on account of the inconvenience felt from the species of heat which they generated. It is also, however, to be observed that the stove, made even upon the most approved principles, requires certain adjuncts and conditions in order to operate healthfully and agreeably.

The accompanying figure represents the Arnott stove in the most improved form given to it by the inventor.

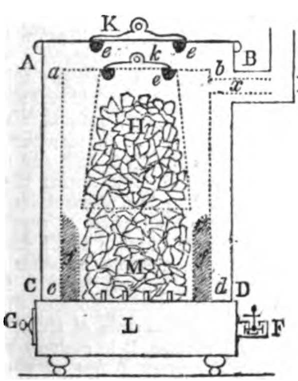

Fig. 3.

We give the description in his own words. 'The complete self-regulating stove may indeed be considered as a close stove, with an external case, and certain additions and modifications now to be described. The dotted lines and small letters mark the internal stove, and the entire lines, the external case or covering. The letters ABCD mark the external case, which prevents the intense heat of the inner stove, *abcd*, from damaging the air of the room. F is the regulating-valve, for admitting the air to feed the fire. It may be placed near the ashpit door, or wherever more convenient. The letters *ff* mark the fire-brick lining of the fire-box or grate, which prevents such cooling of the ignited mass as might interfere with the steady combustion. H is a hopper, or receptacle with open mouth below, suspended above the fire like a bell, to hold a sufficient charge of coal for twenty-four hours or more, which coal always falls down of itself, as that below it in the fire-box is consumed. The hopper may at any time be refilled with coal from above, through the lid, *k*, of the hopper, and the other lid, K, of the outer case. These lids are rendered nearly air-tight by sand-joints; that is, by their outer edges or circumference being turned down, and made to dip into grooves filled with sand, as at *e*, *e*. The burned air or smoke from the fire, M, rises up in the space between the hopper and the inner stove-case, to pass away by the internal flue, *x*, into the other flue, X, of the outer case. L is the ashpit under the fire-bars. G is the ashpit door, which must be carefully fitted to shut in an air-tight manner, by grinding its face or otherwise. M is the coal intensely ignited below where the fresh air maintains combustion, but colder gradually as it is further up. Only the coal in the fire-grate below, where the fresh air has access to it through the fire-bars, can be in a state of active combustion.' The self-regulating valve above mentioned is an ingenious contrivance by which the passage for the air is rendered narrower according to the force of the draught. Dr Arnott describes various other plans of effecting the self-regulation of the combustion.

For sixteen years, Dr Arnott has had his own dining-room warmed by such a stove. The fire in winter is never extinguished, and a uniform temperature of from 60° to 63° is maintained by consuming at the rate of about a ton of anthracite in six months.

A drawer inserted into the heated chamber of the stove would serve for cooking meat, and a pot for boiling might be placed upon the fire-box; it is therefore, as the inventor remarks, peculiarly the *poor man's* stove. Or, by making the space between the two casings water-tight, a *water-stove* is produced, which, besides securing a regulated heat, offers many other conveniences.

In Germany and other northern countries of Europe, the stoves are usually built of brick, covered with porcelain. They are of the size of a large and very high chest of drawers, and usually stand in a corner of the room. The fire is burned in a furnace near the bottom, and the heated smoke is made repeatedly to traverse the structure from side to side, along a winding passage, before it reaches the top, where a pipe conveys it, now comparatively cold, into a flue in the wall. The heated mass of brick continues to warm the room long after the fuel is burned. It is generally sufficient, to warm the stove once a day. The same quantity of wood burned in an open grate, would be consumed in an hour, and would hardly be felt.

Open-fire Stoves.—As a specimen of the numerous plans for combining the advantages of the stove and the open fire, we may take Sylvester's stove or grate, which is thus described in Ronalds and Richardson's *Technology:* 'The fuel is placed upon a grate, the bars of which are even with the floor of the room. The sides and top of these stoves are constructed of double casings of iron, and in the sides a series of vertical plates, parallel with the front facing, are included in the interior, which collect, by conduction, a great portion of the heat generated from the fire—the mass of metal of which these are composed being so proportioned to the fuel consumed, that the whole can never rise above the temperature of 212° Fahrenheit under any circumstances. The sides and top of the stove are thus converted into a hot chamber, offering an extensive surface of heated metal; at the bottom, by an opening in the ornamental part, the air is allowed to enter, and rises as it becomes warmed, traversing in its ascent the different compartments formed by the hot parallel plates, and is allowed to escape at the top by some similar opening into the room.' The Sylvester stove can either be placed in an ordinary chimney

recess, or be made to stand ornamentally forward into the room. The feeding-draught may be either taken directly from the apartment, or brought by flues from the outside of the building.

The idea of having an air-chamber behind and around the fireplace, from which warm air would issue into the room, thus saving part at least of the vast amount of heat that is lost by passing through the wall, is not new, having been put in practice by the Cardinal Polignac in the beginning of last century. But the way to carry the principle out to the full would be to have the open fireplace in a pier of masonry standing isolated from the wall, like a German porcelain stove. A very small fire would keep the whole mass mildly heated. The pier could receive any shape, so as to give it architectural effect; and it might either terminate in the room—the smoke, after parting with most of its heat, being conducted by a pipe into the wall—or it might be continued into the story above, where its heat would still be sufficient to warm a bedroom. An Arnott smokeless grate, set in the pedestal of an ornamental column, which might either stand in front of the wall or in a niche in its depth, might be made the *beau-idéal* of comfort, economy, and elegance.

WARMING BY GAS.

A prejudice arose against gas as a medium of heat, from the first attempts to employ it being made in an unskilful way. But when care is taken to carry off the products of combustion by a pipe, and to prevent overheating, gas-stoves will be found economical and pleasant, and capable of being used in situations where a common stove is inadmissible.

In stoves, gas should always be burnt with the Bunsen burner, which is generally employed by chemists when they make use of gas for heating purposes. It consists of a small brass cylinder, or chimney, set over the gas-jet, like the glass of an argand lamp, with openings near the bottom to allow air to enter. The gas being admitted into this before lighting, mixes with the air, and when lighted at the top, burns with a pale-blue flame. The most complete combustion, and the greatest heat is obtained in this way. We can speak from experience of the porcelain gas-stoves fitted up on this principle by Mr Millar of St Andrew Street, Edinburgh. Smoke, properly so called, there is none. Still it must not be forgot that there is burnt air—a cubic foot of carbonic acid, besides a quantity of watery vapour, for every cubic foot of gas used; and therefore, even with the Bunsen burner, these gaseous products should, wherever it is possible, be conducted away.

A pleasant and very serviceable gas-stove might be constructed by making the casing double, to contain water. It has been ascertained that a gallon of water may be brought to the boiling-point in twenty minutes

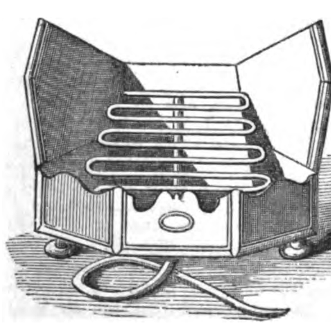

Fig. 4.

by burning 4 cubic feet of gas, which, at 4s. 6d. per 1000 feet, costs only $\frac{22}{100}$ of 1d. The cost of doing the same by a newly lighted coal-fire is more than threefold.

Attempts have been made to combine the appearance of an open fire with heating by gas. Fig. 4 represents such a contrivance. As flame gives out very little radiant heat, the coils of punctured tube are covered with a layer of asbestos shavings, which sparkle and glow in the ignited gas. In other gas-grates, the gas is burned in conjunction with coke.

STEAM AND HOT WATER.

The immediate warming agent in these two methods is the same as in Arnott's and other low-temperature stoves—namely, an extensive metallic surface moderately heated; but instead of heating these surfaces by direct contact with the fire, the heat is first communicated to water or steam, and thence to the metal of a system of pipes. This affords great facility in distributing the heat at will over all parts of a building; and these methods are peculiarly adapted to factories, workshops, and other large establishments. Other advantages are—freedom from dust, and from all risk of overheating and ignition.

Steam.—Steam-warming is generally adopted in establishments where steam-power is used, as the same boiler and furnace serve both purposes. When steam enters a cold vessel, it is condensed into water, and, at the same time, gives out its latent heat till the vessel is raised to 212°, when the condensation ceases. The condensing vessel is usually a cast-iron pipe placed round the wall of the apartment near the floor. In admitting fresh air into the room, it may be made to pass over this pipe, and thus be warmed. The steam is conducted from the boiler by a smaller tube, which may be covered with list or other material, to prevent all condensation by the way; and the admission of the steam is regulated by a cock within the apartment, means being provided for allowing the air to escape. Where a pipe cannot be laid round the room, a coil of pipe may be formed, or the steam may be admitted into a large vessel or into a hollow statue, forming a steam-stove. Allowance must be made for the expansion of the tubes by heat; and they are so arranged that the condensed water is conveyed back to the boiler. One round of iron pipe, of 4 inches diameter, is quite sufficient to warm each of the large apartments or stories of the printing-office from which the present work issues.

There can be no proper comparison between this plan of heating and that of common fireplaces. Coal-fires cannot warm the air in large workshops; the heat is confined to their own immediate neighbourhood; hence the workmen are often obliged to draw near the grate to warm themselves. According to the plan here adopted, every part of the house is equally heated, and the whole of the workmen are as comfortable during the hardest frosts as if they were working in a pleasant summer day. It is difficult to estimate the expense of supplying the heat, seeing that the steam happens to be drawn from a boiler which is always in operation for other purposes. Excellent, however, as the process is, it is for many reasons unsuited to private dwelling-houses.

In calculating how much surface of steam-pipe will be sufficient to warm a room, it is customary to allow about 1 foot square for every 6 feet of single glass window, of usual thickness; as much for every 120 feet of wall, roof, and ceiling, of ordinary material and thickness; and as much for every 6 cubic feet of hot air escaping per minute as ventilation, and replaced by cold air.

Hot Water.—Hot-water apparatus was applied as early as 1777 by M. Bonnemain, in Paris, to warm the hot-houses at the Jardin des Plantes, as well as for the artificial hatching of chickens. It was first introduced into England by the Marquis de Chabannes in 1816, and is now used in many large buildings. It is more economical than steam, except where a steam-boiler is required for machinery; and from this and other advantages, it is generally preferred to steam-apparatus. One of these advantages is, that the heat begins to be

distributed, in some degree, as soon as the fire is lighted, while with steam-apparatus the whole of the water must be at boiling-heat before any steam enters the pipes.

There are two kinds of hot-water apparatus—high-pressure, and low-pressure. In the first, the water is confined, and can be heated to any degree; in the other, it is open to the air, and cannot be heated above 212°.

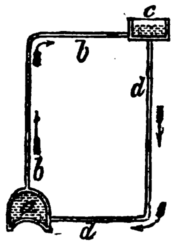

Fig. 5.

Fig. 5 will explain the way in which water is made to carry the heat of a furnace to any part of a building. *a* is a boiler, from the top of which a tube issues, and, after circulating through the building, re-enters near the bottom. At the top of the circuit there is a funnel, or a small cistern, *c*, by which the tubes and boiler may be kept full. When the fire is lighted at the bottom of the boiler, the heated portion of water, being lighter than the rest, rises towards the top through the tube, *bb*, while the colder water from *dd* flows in to take its place. The tube is made to traverse the apartments to be warmed, where it gives out its heat to the air; the returning portion of the pipe is thus always colder, and therefore heavier than the other, so that the circulation is constantly kept up. The warming surface is increased, wherever it is necessary, by coiling the pipe, or by making expansions upon it of various forms, so as to constitute water-stoves.

To avoid the necessity of so large a surface, and such a mass of water as is required at the low temperature the water attains in the pipes of this kind of apparatus, Mr Perkins introduced the high-pressure system. In this the pipe is made comparatively small, but very strong, and is formed into an endless circuit cut off from the atmosphere. The water is heated by making a number of coils of the pipe itself pass through the furnace; and as the whole circuit forms a shut vessel as it were, the temperature may be raised to 300° and upwards, according to the strength of the pipes. This high temperature causes a rapid circulation. A compendious and readily understood specimen of the apparatus, calculated for a house of three stories, is presented in the accompanying engraving. In filling the tube with water, which enters at *b*, care is taken to expel all the air; and at *a* there is an expansion of the tube, equal to 15 or 20 per cent. of the capacity of the whole, which is left empty both of water and air, to allow for the expansion of the water when heated. The arrangement of the pipe may be various: the plan generally followed is to place a considerable coil of it within a pedestal or bunker, with open trellis-work in front, in a convenient part of the room. It may also be made to wind round the room, behind the skirting-board, which, being perforated with holes, will allow of the entrance of the warmed air.

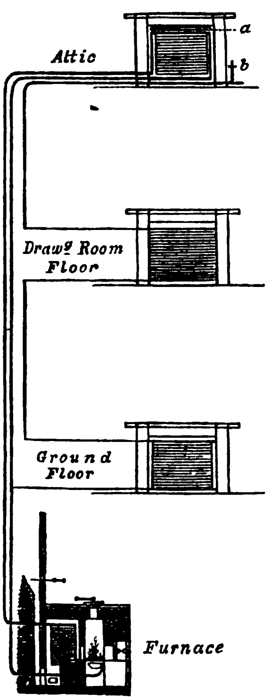

Fig. 6.

The hot-water apparatus has been fitted up by Messrs Perkins and Heath in various public buildings, warehouses, and gentlemen's houses; and, while sufficiently effective for the desired end, it has been proved to be attended with as few drawbacks as any regulated mode of heating whatever. But there is a great obstacle to its general adoption in its expensiveness. The temperature also becomes at times so high as to cause a disagreeable odour. Another objection is its liability to burst; though, from the tubes being of malleable iron, such an accident causes more inconvenience than serious danger.

Conservation of Warmth.

The art of warming embraces not only the production and distribution of heat, but the construction of apartments with a view to prevent its escape. The way to effect this—setting aside in the meantime the necessity of renewing the air—is, in the first place, to make the walls, floor, windows, doors, &c., as impervious to air as possible, to prevent the heat from being carried off by currents; and in the next place, to make them bad conductors of heat. For this last purpose, the walls ought to be sufficiently thick, and, if possible, built of non-conducting materials. Solid iron would make a cold wall; wood, a warm one; and in this respect brick or porous stone is preferable to hard stone. But the chief element in a warm wall is that it be *double*, which every wall in effect is, when it is lined by a coating of plaster, kept apart from the wall itself by the laths. The plate of confined air between the two is the most effectual barrier to the passage of the heat outwards that could be contrived. By making iron walls double or cellular, with a lining of plaster, they might be rendered as warm as wished. Windows are a great source of cold, not merely by admitting cold air, but by allowing the heat to pass by conduction through the thin glass. The air of the room that touches the window is robbed of its warmth, and is constantly descending in a cold stream towards the floor. There is thus a cold influence felt from a window, however close it is. This is partly arrested by window-blinds, shutters, and curtains, which check the flow of the air, and retard its carrying power. But a far more effectual plan is to have double windows: either two frames, or double panes in the same frame. The loss of heat by a double window is said to be only one-fourth of that by a single. Double windows are considered essential in countries where the winters are rigorous.

By carrying those principles far enough, we might succeed in well-nigh imprisoning the heat, and thus produce a house of ideal perfection, so far as mere temperature is concerned. But for the habitation of living beings, another condition, seemingly antagonistic to the former, is no less requisite—'air, as free as that on a mountain-top.' In general practice, the two hostile conditions are not so much sought to be reconciled, as compromised; and then, as usual, neither object is well attained. Circulation of air is got accidentally, through the imperfections of structure in our rooms—through the chinks and bad fittings of the windows, doors, floors, and the uneconomical fashion of our fireplaces. Were houses much better constructed than they are, the inmates would in many cases be suffocated outright, as they often partially are with the degree of perfection we have already attained. Neither the airing of our houses, nor the art of building them solid and warm, can advance to perfection, until the former be no longer left to chance, but be in every case secured by special apparatus capable of direct control. We now proceed to consider how this is sought to be attained; confining ourselves still to the leading principles, and only noticing a few of the specific plans that have been put in practice.

VENTILATION.

The importance of constantly respiring pure air is more fully considered in the paper on PRESERVATION OF HEALTH. For our present purpose, it will be sufficient to bear in mind the following facts. Fresh air is chiefly made up of two gases, which are everywhere found to be in the same proportion: nitrogen forming about four-fifths of its bulk, and oxygen forming one-fifth. It also contains a very variable quantity of vapour of water, and a smaller but pretty constant quantity of carbonic acid gas (see CHEMISTRY)—namely, 1 part in 2000 by measure. When a portion of this air has been once breathed, it is found to have undergone several changes, which render it unfit to be breathed again. The chief vitiation consists in a portion of the oxygen being abstracted, and nearly as much carbonic acid gas substituted for it, the carbonic acid having been formed by the oxygen uniting with the carbon of the blood. The average quantity of carbonic acid in expired air or breath is found to be 4·3 per cent. by measure. Now this gas, when taken into the lungs, is a poison, and tends to arrest the vital processes. Like other poisons, however, it can be rendered harmless by *dilution*. The small proportion naturally existing in the atmosphere is perfectly innocuous, and may be considerably increased without sensible effect. But it is decidedly prejudicial to breathe for a long time air containing 1 measure in 100 of carbonic acid, especially if the carbonic acid has been formed by breathing or combustion, at the expense of the oxygen of the same air; and it is considered desirable that the proportion should never exceed 1 in 500. We may assume, then, what is near the truth, that 20 cubic feet of air pass through the lungs of a man in an hour. To reduce the poison of this to 1 per cent., at which point it is barely respirable, it requires to mingle with as much fresh air as will make a mixture of nearly 100 cubic feet; and to make the dilution at all safe, it must be carried five times as far. In other words, the respiration of one human being vitiates hourly about 500 cubic feet of air.

In addition to carbonic acid, expired air contains an undue amount of watery vapour. Minute quantities of animal matters are also exhaled with the breath, which in close ill-ventilated apartments form a clammy deposit on the furniture and walls, and, by putrefying, become organic poisons.

A further necessity for the constant renewal of fresh air arises wherever lights are burnt. The deteriorated air of a fire goes off by the flue, but lights are generally burnt where the products must mingle with the atmosphere of the apartment. Now, a pound of oil in burning consumes the oxygen of thirteen feet of air, and produces a large amount of water in vapour, and also of carbonic acid. Every cubic foot of gas consumes the oxygen of ten feet of air, and forms at least one foot of carbonic acid, besides watery vapour, sometimes mixed with sulphurous fumes.

There is in so far a natural provision for preventing us from being poisoned by the products of our own respiration. The breath, being warmer, and thus lighter than the surrounding air, rises upward as it issues from the mouth, and thus saves us, without trouble or thought, from all risk of inhaling it a second time. But the process is perfect only in the open air: under a close roof, the vitiated air is arrested and accumulated, and is soon spread through the whole room.

In an ordinary apartment heated by a common open fire, there is an imperfect kind of ventilation always going on by means of the fire, which draws in through the door, windows, and other apertures, fresh air to supply that consumed by itself, or which the chimney-draught otherwise carries off. This is imperfect, in as far as the draught may only clear a certain space near the bottom of the room, between the door or windows and the fireplace, leaving the most foul and heated portions floating above the level of the chimney-breast; also, in as far as it only operates when there is a fire, and therefore not in the summer-time. It therefore becomes desirable that a regulated mode of ventilation, calculated to be thoroughly and at all times effectual, should be applied to ordinary apartments. It is not less necessary that churches, court-rooms, theatres, and all large halls in which great numbers of persons assemble, should be subjected to a mode of ventilation, regular, certain, and complete. Nor is it unworthy of notice that a regular means of ventilation is also required in stables, cow-houses, and other places where valuable animals are kept.

Ventilation consists of two operations—the removal of the foul air, and the introduction of fresh. Though neither operation can go on without the other going on at the same time, it is convenient to consider the two separately.

The agents employed in removing the air from apartments are chiefly two: that by which nature effects the ventilation of the earth on a grand scale (see METEOROLOGY)—namely, the draught of ascending currents produced by difference of temperature; and mechanical force, such as pumping. The former is the more common, and is the only one applicable to private houses.

The column of air in the chimney of a lighted fireplace being expanded and comparatively light, exerts less than the prevailing pressure on the air immediately under and about its base. On the principle, therefore, explained in HYDROSTATICS and PNEUMATICS, the air below and around it pushes it up, and flows in to take its place; the velocity of the movement being in proportion to the height of the chimney and the degree of heat. Thus, although it is often convenient to speak of the air being *drawn* or *sucked* into the chimney, the force does not lie in the chimney, but in the greater pressure of the air behind. If we were accustomed to look at the movement in this light, it would tend to do away with many of the confused and erroneous notions entertained on the subject of chimney-draught, and on ventilation generally.

Wherever, then, there is a heated chimney, there is a means of removing the foul air. And in rooms moderately lofty and spacious, with windows and other fittings not closer than usual, and a chimney-mouth of the usual width, there is little risk, when there are only a few inmates, of any serious vitiation of the air. The heated breath that ascends to the ceiling has time to diffuse itself gradually, and be drawn in a diluted state into the currents that are setting from all quarters towards the chimney. These currents, however, are one great objection to this mode of ventilation, as they consist in great part of cold air that has just entered by the doors and windows, and are strongest where the inmates sit to enjoy the fire.

The ascent of foul air to the top of the room dictates its exit in that direction, rather than low down at the mouth of the chimney. It is conceived by some that the carbonic acid of the breath, from its greater weight, must be chiefly at the bottom of the room; but this is a mistake. The heated breath ascends instantly, because it is, as a whole, lighter than the air around it; and the carbonic acid in it does not tend to separate from it and fall down by its superior weight, but, by the law of the diffusion of gases (see METEOROLOGY), seeks to spread itself equally all over the room, and would do so though it were lying at first on the floor. It is on the principle of the foul air ascending at first to the top of a room, that Dr Arnott's ventilating-valve is contrived. The valve may be used to supplement the open-fire draught in small and crowded apartments, and is essential where the fire is burned in a close stove or in the smokeless grate. The valve is represented at *v*, fig. 1. An aperture is cut in the wall over the chimney, as near to the ceiling of the apartment as may be convenient. In this is

suspended a valve, capable of opening inward to the chimney, but not in the other direction, by which means a return of smoke is prevented. The valve is so balanced on its centre of motion, that it settles in the closed position, but is easily opened. A flap of thirty-six square inches is sufficient, where there is good chimney-draught, for a full-sized room with company. This simple apparatus may be painted, or otherwise made ornamental. It operates by virtue of the draught in the chimney. Whenever that is active from the presence of a fire, the valve is seen to open inwards, and a stream of air from the top of the apartment passes through into the chimney, and is carried off. The operation is precisely equivalent to the stream of air always passing into a chimney between the fire and the mantel-piece, but has the great superiority of draining off the most impure air in the room. A wire descends to a screw or peg fixed in the wall, by which the opening of the valve may be limited or altogether prevented. This is a far more efficient plan of ventilation than an open window, or an opening in the wall near the roof, leading merely to the outer air; where there is an open fire in the room, such openings rather admit a rush of cold air than let out the foul.

There is generally more or less draught in a chimney even without a fire, from the air within being slightly warmer than that without; and this action might be strengthened by burning a jet of gas within the ventilating aperture at *v*. Where a house is to be built new, some recommend having special ventilating-flues in the walls, separate from, but close to the fire-flues, so that the air may be heated, and an ascending current produced. In weather when fires are not required, the draught can be maintained by gas-jets at the entrances to the vents. This plan of causing a draught by gas is applicable to churches and apartments without fireplaces.

Where a fire is burnt for the express purpose of producing a current of air, it is called ventilation by *fire-draught*. The plan has been exemplified with success in mines, where a fire being lighted at the bottom of a shaft, air is drawn off in all directions around, and sent up the shaft; to replace which, fresh air is constantly pouring down other shafts.

Mr Fleming of Glasgow applied the same principle with great success to the ventilation of a large pile of buildings in that city which was densely crowded with poor inhabitants; and in doing so, he availed himself of the chimney-stalk of an adjoining factory. From an upper corner of each of the apartments, he led a metal tube, of about an inch and a half in diameter, which, passing into the adjacent gallery, there met and joined a general pipe, nine inches in diameter, suspended immediately under the ceiling. One of these general pipes passed along each gallery in the four stories, and the whole joined in one vertical tube at the end of the house, communicating at the bottom with the base of the chimney-stalk. It follows that, when this flue is active—and practically it is so day and night—a draught is established upon the air-contents of every room in the house.

Many of our large buildings, as St George Hall in Liverpool, and the Millbank Penitentiary, London, are ventilated by fire-draught. Fig. 7 shews an arrangement by which a school or church may be ventilated: *aa*, the flooring perforated with holes, through which air, warmed by hot-water pipes, passes to the interior. The ceiling, *bb*, is perforated, leading to a chamber which communicates with a vertical flue, *cc*; which leads to the fire-place of the warming-apparatus, situated at the foot of a flue, *ed*. As the only air which reaches this must pass from *cc*, a constant current is maintained therein, and also through the apertures in the ceiling. Dr Reid has exemplified this method, first in his own class-room in Edinburgh, and afterwards in various public buildings.

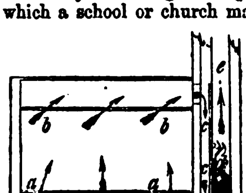

Fig. 7.

A description of his arrangements in the House of Commons involves the principles of heating, or rather of temperature—regulation, as much as those of ventilation. 'The air'—we quote the account given by Drs Ronalds and Richardson of this much-agitated affair—'is supplied from Old Palace Yard to the basement of the building, passing first through a fibrous veil 42 feet long by 18 feet 6 inches deep, for the exclusion of visible soot, it arrives at the heating-apparatus, consisting of large chambers intersected by steam-pipes, and proceeds from thence to other chambers, where it can be mixed with cold air, and brought to any required temperature. The floor of the house is double, and the space below the floor can be connected by means of valves with the hot-air chamber. The floor is perforated by a great number of apertures, and these are covered with hair-cloth, so that the hot air, in escaping from the floor into the body of the house, is infinitely divided, and no perceptible current is experienced. Having performed its functions, the vitiated air ascends to the ceiling, which is also double and perforated, in the same manner as the floor, whence it is carried off by the draught created by a powerful fire under a chimney-shaft erected in another part of the building.'

'The plan adopted by Sir Charles Barry for warming and ventilating the House of Peers, the royal ante-chamber, and the public lobby, differs from that just described both as respects the admission of the air and its removal. The floors of the rooms are impervious, and are heated in the first instance simply by the passage of hot air below them; the hot air then escapes by passages along the external sides of the rooms to the ceiling, which is divided into two compartments—the one for the admission of the warm air, entering at the sides, and the other for the exit of the vitiated air. The warm air, after passing below the floor to the roof, becomes somewhat cooled, so that its temperature on entering the ceiling is a few degrees lower than that actually present in the room; it consequently descends to the level, at which it is at once heated again; and deteriorated by combustion, respiration, &c., rises through the centre of the room, passing through the ceiling to a foul-air chamber above, whence it is conducted to a chimney, and carried off by the peculiar motive-power first suggested by Dr Richardson to the production of draught. This power consists of a jet of steam, which, when produced under a pressure of 32 pounds to the square inch, is capable of setting 217 times its bulk of air in motion; 10,000 cubic feet of air are thus gradually diffused through the three apartments per minute; no draught of any kind is perceptible; and no inconvenience is experienced from dust or other solid particles being carried mechanically forward by the air, as is said to be the case when the air enters from below.'

In other cases, as at the prison in Millbank, warm air is admitted at the ceiling, and carried off by the draught of a chimney in connection with the sides or lower part of the rooms.

In these last-mentioned instances, the apparatus provides as well for the admission as for the removal of air. In ordinary dwellings, no special provision is in general made as to admission. It is, in fact, not absolutely necessary; for the removal of a portion of the air of a room never fails to secure the entrance of a fresh supply somewhere. Whenever the chimney-draught or other means removes a little of the pressure inside the room, the pressure without forces air through every opening and chink; and even, were there no actual openings, would force it through the porous substance of the structure—such as mortar, and even wood

itself. But this irregular source of supply has various inconveniences. It often requires more force to strain the air in this manner than the draught is possessed of, and then the chimney smokes; it is smoke produced by this cause that is curable by opening the door or window. Another objection is, that impure air is often thus drawn into rooms from the lower parts of the building and from drains about the foundation. For these and other reasons, there ought, in all cases, to be a free and legitimate entrance provided for fresh air, so as to give a control over it; and this entrance should be independent of the windows. It is a much disputed point whereabout in a room the air should be made to enter—some advocating openings for it near the floor, others near the ceiling; and it must be confessed that neither method has yet been rendered unobjectionable. One essential thing is, to prevent the air from rushing in with a strong current, by passing it through minute holes spread over a large space. A tube, for instance, leads from the outer air to a channel behind the skirting, or behind the cornice, and the air is allowed to issue into the room through minute holes or through a long, narrow, and concealed opening covered with perforated zinc or wire-gauze. The passage or tube leading from outside the wall can be more or less closed by a valve regulated from the inside.

But the great difficulty lies in the coldness of the air directly introduced from the outside, whether by the doors and windows, or through channels in the walls; and all such plans of ventilation must be considered as imperfect make-shifts. There can be little doubt that our descendants will look upon them as little less barbarous than we now think the arrangements of the palace of Cedric the Saxon, and the ventilation of Rowena's boudoir, as described in *Ivanhoe.*

The fresh air ought in every case to be warmed before being admitted, or, at least, before being allowed to circulate in a sitting-room. In the smokeless grate (fig. 1), the air is led directly from the outer atmosphere into a channel (1, 2) underneath the hearth, and escaping below the fender and about the fire, is warmed before spreading through the apartment. With stoves and heated pipes, the air should enter about the heated surface; in stoves on the cockle principle, the fresh air, as it enters, is made to pass between the casings of the stove. With an open fire, a very feasible plan is to make the fresh-air channel pass behind the fireplace, and allow the warmed air to escape from concealed openings about the chimney-piece and jambs, or from behind the skirting. In Condy's Ventilating-grate, the fire-box is constructed of hollow pieces of fire-brick communicating with the external atmosphere and with the room.

For a house with fireplaces of the usual construction, perhaps the simplest and most effective expedient is to admit the fresh air into the entrance-hall, and there warm it by means of a low-temperature stove or by water-pipes; its passage into the several rooms can then be provided for by regular channels, behind the skirting or otherwise. In America, perforations are frequently made in certain parts of the doors, before which silk curtains are disposed, so as to temper the currents. It is almost unaccountable that in this country the plan of warming the lobby and staircase is so seldom resorted to. To say nothing of the comfort thus diffused through the whole house, and the benefit in point of health, especially to weakly constitutions, the economy of the arrangement is beyond dispute. In the sitting-rooms, not more than one-half the usual quantity of fuel requires to be burned in the open fires; and in the bedrooms, as a rule, fires are rendered altogether unnecessary in the coldest weather. It ought to be observed, that when air is admitted by a regular and free channel, comparatively little is strained in by the windows and other byways.

Ventilation by Fans and Pumps.—The fan-wheel has been for many years used in factories, to which it is particularly applicable, from the readiness with which it can be kept in motion by the engine. It is essentially the same as the barn-fanners; the air is drawn in at the centre of the wheel, and flies off at the circumference by centrifugal force. The fan is placed at the top of a flue, into which branches from all parts of the establishment proceed; and when it is set in motion, it draws off the air from every apartment communicating with it. Dr Arnott observed, that in the fan-wheel as well as in the air-pump or bellows invented by Dr Hales, a great deal of power was wasted by 'wire-drawing' the air—that is, making it squirt through small valves or other narrow openings. He has shewn how this may be obviated by the following form of a ventilating-pump (fig. 8): *efhg* is the outer cylinder; the piston consists of another cylinder, *abdc*, suspended within it like a gas-holder, and dipping into water, WW. The outer cylinder is closed at top and bottom, but has at *e*, *f*, *g*, *h*, curtain-valves of oiled silk resting against wire-gauze, those at *e* and *g* being suspended outside, at *f* and *h*, inside. As the cylinder-piston, A, descends, the curtains at *g* open, and allow the air to issue, while air is drawn in at *f*; when it begins to ascend, the former valves close, and air is now drawn in at *h*, and expelled at *e*. Thus air is continually entering at the side *fh*, and being expelled at the side *eg*. By connecting, then, the side *fh* with the outer air, and the side *eg* with a system of pipes leading to the apartments of a building, fresh air may be forced in, and the foul air blown out; or by reversing the connection, the foul air may be pumped out of the apartments, which of itself will draw in fresh air, as before explained. Very little power is required to move the piston up and down; in the York Hospital, where such a 'Gasometer Ventilating Pump' has been in highly successful operation for several years, the motive-power is derived, by a very ingenious contrivance, from the descent of the water used in the establishment from a high reservoir to the lower parts of the building; the descent of every pint sends 250 cubic feet of air into the hospital. 2000 feet a minute is the rate of supply.

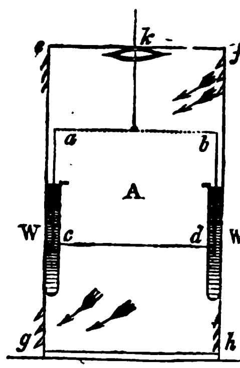

Fig. 8.

Transference of heat from the used air to the fresh.—We practise this kind of economy when in cold weather we breathe through the folds of a woollen handkerchief. The breath, raised to the temperature of the blood, leaves a great part of its heat in the handkerchief as it passes through; the cold inspired air absorbs this heat again, and enters the lungs considerably warmed. The same thing is more effectually done by the wire-gauze respirators invented by Jeffrey.

This is essentially the principle of the caloric-engine, or, more properly, hot-air engine, lately brought forward by Captain Ericsson of New York; but which is merely a copy of the invention of Dr Stirling of Perth, patented as early as 1816. The heated air, which has moved the piston, escapes through a body of thin metal slips or wires, which it heats; the fresh air as it enters re-absorbs the heat so deposited, and thus requires less heat from the furnace to bring it to the requisite temperature.

Whatever difficulties—or impossibilities, as some maintain—there may be in the way of turning this transferred heat into a fresh source of power, nothing seems simpler, in theory at least, than to economise heat in this manner

for the warming of dwellings and similar purposes. The idea originated with Dr Arnott, many years ago,

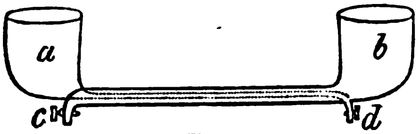

Fig. 9.

who thus illustrates it in the case of water: Suppose *a* a vessel of boiling water, with a thin metallic tube issuing from the bottom, and having a stop-cock at *d*; and *b* a similar vessel of water at freezing, the tube of which is larger, and envelops the other. When both are flowing simultaneously, the hot water, if the tube is long enough, will have lost all its excess of heat before getting to *d*, while the counter-current will have gained all that the other lost. In an experiment with tubes six feet long, the boiling water from *a* issued from *d* at 34°, and the freezing water from *b* issued from *c* at 210°. It is clear that if *a* were a bath, the warm water in it, after being used, might in flowing out be made to heat the cold water from a reservoir, *b*, flowing into another bath below *c*. We are not aware that the principle has ever been acted upon; but the possible economy of heat is obvious, and it only requires mechanical ingenuity to realise it.

It will at once strike the reader how desirable it would be to do the same with the impure heated air which we are obliged to eject from our dwellings. Where the ventilation depends upon the draught of a common chimney, it would seem impossible to bring the entering air in contact with that which is escaping; but where the mechanical force of a pump is employed, nothing seems simpler than to make the two currents run counter to one another for a certain distance in close contact through a system of tubes. The smoke even, which, with the most economical arrangements, still issues from the flues at a temperature considerably above that of the building, might be drawn into the current along with the foul air of the apartments, and the whole reduced nearly to the temperature of the atmosphere before being allowed to escape. Of course, there must be loss in the transference; but a large percentage would be saved, and the consumption of fuel would be reduced by that amount. Were this 'double-current ventilation' applied to churches, ball-rooms, theatres, &c., where thousands of persons are assembled, Dr Arnott believes that 'no other heating-apparatus will be required but the lungs of the company.' The plan seems available for private dwellings only where a number are arranged in one pile on the 'flat' system, as practised in Paris and Scotland, and as exemplified in Victoria Street, Westminster.

Even though such painstaking plans of economising heat might not pay at the present cost of fuel in this country, it is pleasing to think that there is such a resource in reserve. It is not with all countries as with us; and even our stores of coal are not inexhaustible. It is an unworthy, and, in the real sense of the word, an inhuman maxim, that bids us 'let posterity look to itself.' If the absorbing passion for present gain will not let us begin practising economy now, we may at least seek to devise and perfect plans to be in readiness when the necessity comes. It is not uncommon to hear the argument, that before the coals are done, something else will be discovered as a substitute. We are at a loss to imagine what the something is to be, unless it be the ingenuity to make the fuel that is now wasted in a year, last a hundred; and this we believe to be quite possible.

PREVENTION OF SMOKE.

The smoke arising from the furnaces employed at factories has been long felt as a great nuisance in most manufacturing towns, polluting, as it does, the pure air of heaven, and begriming every exposed object within the range of its influence. Those employing furnaces have also become generally aware that smoke is only a volatile form of fuel, and that if either less of it were generated, or if, when generated, it could be consumed, there would be a great saving in the expense of raising steam. These circumstances led to various devices for the combustion and prevention of smoke, and of late it has been rendered obligatory on the proprietors of all works to adopt means for that end.

The nature of smoke has been already explained. It is produced in greatest quantity when fresh fuel is added; more gas is produced than there is in general air to consume; and the coldness of the fresh coal makes its temperature too low to burn, though the air were abundant. When a sufficiency of air is admitted by opening the door of the furnace, the additional cold only still further lowers the temperature of the gases, and cools the boiler. The chief points aimed at in the various plans for overcoming this difficulty are—to introduce jets of air into the flame behind the furnace, so as to produce more perfect combustion, on the principle of the argand burner; to make the volatile matter of the fresh fuel pass over the hotter parts of the fire; and to add the fresh fuel in a gradual and regular way. We can notice only a few of the numerous contrivances that have been tried.

Mr Howard's invention, which is closely allied to that of Williams, is represented in the accompanying woodcut: *d* is the boiler surrounded by common flues; *a* is a coking-plate; *b*, the body of the furnace, with the ashpit beneath, which is closed against the admission of air; *e*, a fire-bridge, like that of a reverberatory furnace, and *c*, a space for the regulated admission of heated air. The coal is first coked on the coking-plate, and then pushed over on to the grate-bars, where there always exists a bright surface of burning coke. The gases generated in coking a fresh portion of coal pass over this heated surface before they come in contact with a fresh supply of warm air at *c*, and thus an almost perfect combustion of smoke is the result.

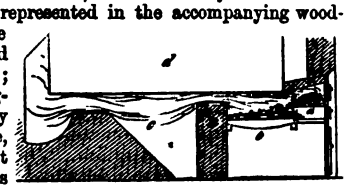

Fig. 10.

A somewhat similar plan is that of Stevens, which has been largely introduced, and has the favourable opinion of practical men; it is easily adopted, and not liable to get out of repair. The diagram, fig. 11, shews its application to a Cornish boiler, *aaaa*. *b* is the furnace-bar; *c*, the ashpit. There is a space between the end of the furnace-bar and the fire-bridge, *f*; below this space is another set of furnace-bars of smaller area, on which the red-hot cinders fall from the upper bars. The air passing along the ashpit, enters the furnace between two strata of fire, and thence between the caloric-plate, *d*, and bridge, *f*. The air is thus so intensely heated as to produce the entire combustion of the gases and prevent smoke.

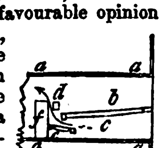

Fig. 11.

One plan in extensive use, and said to be successful, is that of 'alternate firing.' In this contrivance two fireplaces are used, both leading into a space called the mixing chamber. While one furnace is newly 'fired,' the other is in a state of high combustion, so that the gases pass from it into the chamber at an intense temperature, and there meeting with the smoke from the other furnace, raise it to combustion heat. There are numerous modifications of this principle of two fires fed alternately.

Of plans depending upon the slow and regular admission of the fresh fuel by means of machinery, it will be sufficient to notice that of Jukes. His grate-bars are

endless chains passing over rollers, and moved forward about an inch per minute. The coal employed is common siftings or screenings, which is heaped on the bars outside the furnace-door, which slides upwards. The door is left a little open, and by passing under it, the small coal is spread uniformly over the bars. The air is constantly supplied through the bars directly to the fuel while burning, and in this way perfect combustion is obtained. The bars, being slowly moved on, carry the ashes to the ashpit, which lies at the back of the grate. Jukes's apparatus was applied to the furnace of the engine which prints this work in 1848, and has been completely successful; it is rare that a single particle of smoke can be seen issuing from the chimney, and the saving in coal and attendance is decided.

Without any essential alteration on the common arrangements of a furnace, much may be done for the prevention of smoke by the expedient of having a double fire-door, with the inner plate pierced with numerous small holes. A self-regulating valve in the front plate admits more or less air, according to the state of the fire; and this air, heated between the plates, passes in small jets through the holes, and consumes the hot vapours. It is also found that a proper proportion of parts in the furnace, flues, &c., will of itself secure the absence of smoke.

LIGHTING.

Artificial lighting depends upon the fact, that solid bodies when heated to a certain degree, become luminous or *incandescent*. The luminosity begins at the temperature of about 800°; and as the heat is increased, the red passes into a white of greater and greater brilliancy.

Gaseous bodies, however hot, give little or no light. Air hot enough to make a body held in it red, is itself not luminous; and the flame of hydrogen gas, which, when burnt in oxygen, produces the greatest heat known, is barely visible. In order to produce light, then, we must have a highly heated solid substance. In practice, this is best obtained by burning volatile compounds of carbon and hydrogen. The combustion of the hydrogen produces intense heat, and the particles of solid carbon, before being themselves burnt, become white in the hot gas.

While pure carbon may be used as fuel for producing heat, carbon and hydrogen united, and burning in the shape of flame, produce most light, because the combustion is more rapid, and the heat more intense. Carbon and hydrogen combine in a variety of ways, and produce a numerous class of compounds, called *hydro-carbons*, some of which are solid, some liquid, and others gaseous, but mostly capable of being vaporised by heat. A number of natural products, such as the animal and vegetable oils, tallow, wax &c., are altogether composed of such compounds, and can be vaporised or distilled without leaving any solid residue. These form the readiest sources of light, because the substances may be distilled or vaporised by the heat of the flame that produces the light, as in the case of a candle. Coal, on the other hand, which is only partly vaporisable, must be distilled by the heat of a furnace, and this makes the distinction between gas-illumination and illumination by lamps or candles. In both cases, the source of light is the combustion of vaporised hydro-carbons.

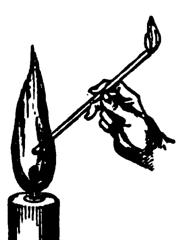

Fig. 12.

Structure of Flame.—The flame of a lamp or candle, or simple gas-jet, consists of a hollow cone, in the centre of which there is no combustion. The central space appears dark only by contrast with the luminous cone which surrounds it. It consists, in reality, of transparent invisible compounds of carbon and hydrogen, which are constantly rising in vapour from the wick. If a glass tube, open at both ends, be held obliquely in the flame of a candle, with its lower extremity in the dark central space above the wick, it will conduct away a portion of the combustible vapour, which may be kindled like a gas-jet at its upper end, as represented in fig. 12. This dark portion of the flame may be called *the area of no combustion.*

The luminous cone which envelops the dark space is *the area of partial combustion.* The oxygen of the atmosphere penetrates to this depth, but not in sufficient quantity to oxidise or burn both the carbon and the hydrogen; it therefore unites with the hydrogen, for which it has the stronger attraction, and leaves the carbon free. The outer cone is named *the area of complete combustion*, because there the carbon meets with sufficient oxygen to burn it entirely. The light is produced in the area of partial combustion, where the carbon is set free from the hydrogen in the form of solid particles, and is heated to whiteness by the combustion of the hydrogen. The combustion of the carbon in the outer cone, by which it is converted into carbonic acid gas, produces heat, but so little light as to be barely traceable.

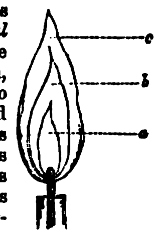

Fig. 13.

a, Area of no combustion.
b, Area of partial combustion.
c, Area of complete combustion.

That carbon exists in a solid state in the white part of a flame, is readily shewn by holding a piece of white earthenware into it, which becomes coated with carbon in the form of soot. No soot is deposited in the dark or no-combustion area of the flame, because there the carbon is in chemical combination with hydrogen, forming a gas. The carbon becomes solid only when the hydrogen deserts it, as it were, to unite with oxygen.

The highly illuminating power of compounds of hydrogen and carbon is thus traced to the fact, that *their hydrogen and carbon do not burn simultaneously, but successively, and in such a way that the one heats the other white hot.* It is quite possible to make them burn simultaneously; but when they do, the light evolved is very feeble. This is seen in the Bunsen burner alluded to, p. 470.

ILLUMINATION BY CANDLES AND LAMPS.

In principle, these two modes of lighting are the same. The essential parts of a lamp are a vessel containing liquid fat, from which a portion rises gradually by capillary attraction through the wick to the flame. In a candle, the solid fat below the flame is melted into the form of a hollow cup, which forms a reservoir for the liquefied portion, and becomes thus a tallow lamp. As the manufacture of candles is described in CHEMISTRY APPLIED TO THE ARTS, our remarks here may be confined to lamps.

The chief difficulties that attend the use of lamps as a source of light are—First, to procure the complete combustion of the oil, so as to keep the flame from smoking; and second, to prevent the level of the oil in the reservoir from sinking as the combustion goes on. The round cotton-wick used in the old simple form of lamp was always attended with smoke and smell. The oils and fats are exceedingly rich in carbon, containing 70–80 per cent. of that element, and only 10–12 of hydrogen. The round thick column, then, of oil-vapour rising from the wick of an old-fashioned lamp, presents too little extent of surface to the air; the oxygen of all the air that can get access is chiefly taken up in burning the hydrogen, and a large proportion of the carbon ascends in the burnt air as smoke. The most essential improvement in this respect is what is known as the Argand burner, from the name of its inventor. In

this the wick is in the form of a ring. The flame is thus a hollow cylinder, with a current of air ascending through the inside, so that the burning surface is doubled.

Another part of Argand's improvement consisted in placing a glass cylinder as a chimney over the flame, by which means the flame is steadied and a draught created.

Subsequent improvements have had for their object to deflect the currents of air from their parallel course, and make them strike against the flame. With this view, glass chimneys are often made to contract a little above the top of the flame. In what is called the Solar Lamp, the deflection takes place lower down, about half an inch above the top of the wick. The flame is there made to pass through an aperture in a metallic cap fitted on the top of the burner, as represented in figure 14. By this arrangement, the air is both made to

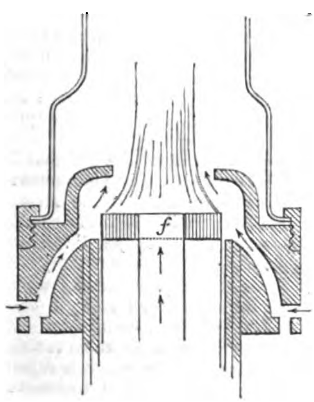

Fig. 14.

impinge against the outside of the flame, and the flame itself is forced inwards against the ascending column of air in its centre. The coarser oils can thus be burnt without smoke, and with great brilliancy of flame. Instead of the metallic cap, or flat metallic ring, glasses are now made of the shape represented in fig. 15, which serve the same purpose; they are, however, liable to break, if care is not taken.

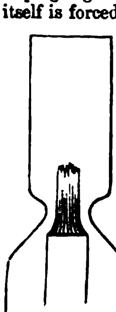

Fig. 15.

Another contrivance for making the air impinge against the flame, is to have a wire, *b* (fig. 16), ascending from the hollow space in the argand burner, and supporting a metal disc, or button, *a*, in the heart of the flame; this throws the ascending air in the inside against the flame, and makes it spread out like the cup of a flower. By combining these and similar contrivances, lamps are now constructed that burn rectified oil of turpentine (camphine) and other volatile oils, which otherwise burn with much smoke.

Fig. 16.

The second imperfection attending lamps, that, namely, arising from the change of level in the oil, is sought to be remedied by making the vessel wide and shallow; and in order that it may cast as little shadow as possible, it is disposed in the form of a wide ring round the burner. Other lamps are constructed on the principle of the bird-fountain, explained in PNEUMATICS. But the most effectual plan is to have the oil pumped up from the foot of the lamp to the wick by mechanical means. The most perfect mechanical lamp is that of Carcel, a Frenchman, in which the oil is pumped up by clockwork; it is, however, by far too expensive and difficult of repair, to be adapted for ordinary use. The French Moderator Lamp (fig. 17) is much simpler, and appears to overcome the difficulties of the case. The body of this lamp consists of a cylinder or barrel, B, the lower part of which contains the store of oil. On the top of the oil rests a piston, P, which is constantly pressed down by a spiral spring, situated between it and the top of the barrel. The piston is represented in the figure as resting on the bottom. Through the piston is inserted a small tube, which passes up to the burner at the top; and the pressure of the spring on the piston

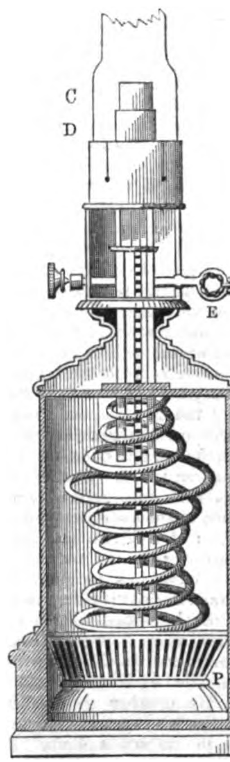

Fig. 17.

Fig. 18.

causes a constant stream of oil to rise up through this tube and feed the wick, C. What is not consumed, flows over the burner, D, and back into the barrel above the piston. It is above the piston also that fresh oil is introduced. When the piston has reached the bottom, it is wound up again by a rack and pinion, E; and a vacuum being thus formed, the oil above it is forced to the underside through a valve-kind of contrivance round its edge.

It is obvious that in this machine the flow of oil will be greatest when the piston has been newly wound up, and the spring is at its greatest tension. This inequality is regulated, or *moderated*—hence the name of the lamp —by an extremely ingenious contrivance. The tube through which the oil ascends (represented in fig. 18 on an enlarged scale), consists of two parts—a narrower, *b*, fixed to the piston, and rising with it, and a wider, *c*, fixed to the burner, and forming a sheath into which the other ascends. Within the upper tube is placed a

rod or wire, G, which descends so as to enter only a short way into the tube *b*, when the latter is drawn down to the full, as represented in the fig. Now, the effect of the rod within the narrow tube at *r* is to retard the passage of the oil; and it is evident that the effect will be greater the further the tube *b* is pushed up, because the narrow part is then made longer. The obstruction thus increases and diminishes with the force of the spring, and the flow of oil is rendered equable.

GAS ILLUMINATION.

The existence of an inflammable air, as a natural production, has been known from a period of great antiquity. It was observed to issue spontaneously from fissures in the earth; and has been employed in such situations, as a source of light and heat, both in ancient and modern times. This natural gas is also found in abundance in some coal-mines, where it constitutes the 'fire-damp' so destructive to the miner.

The artificial production of an inflammable air, by distilling coal in a close vessel, is first mentioned in a letter by Mr Clayton, rector of Crofton, Yorkshire, addressed to the Royal Society, May 12, 1688. Though well known to chemists from this time, it was only esteemed as a philosophical curiosity until the year 1792, when Mr Murdoch, an engineer, then residing at Redruth, in Cornwall, prepared coal-gas on a scale sufficiently large to light up his own house and office. In 1798, he was engaged to put up his apparatus at the manufactory of Messrs Boulton and Watt, Soho, near Birmingham, where he continued to experiment, with occasional interruptions, until the year 1802. It does not appear, however, that much attention was excited by these first efforts at gas-lighting, except among a very few scientific individuals, until the general illumination at the peace of Amiens afforded an opportunity for a more public display. On this occasion, the front of the manufactory was brilliantly lighted up by the new method, and it at once attracted the wonder and admiration of every one who saw it. 'All Birmingham poured forth to view the spectacle; and strangers carried to every part of the country an account of what they had seen. It was spread about everywhere by the newspapers; easy modes of making gas were described; and coal was distilled in tobacco-pipes at the fireside all over the kingdom.'

By the exertions of a Mr Winsor, a company was formed in 1804 for supplying London with gas; but it struggled for many years with the difficulties at once of inexperience and public prejudice. At length most of these difficulties were overcome, and gas-lighting, especially for streets and public buildings, began to spread over the kingdom. Its progress in dwelling-houses was at first retarded by the injurious effects of the impurities it contains in its crude state. But science has shewn how these may be effectually removed, and well-made gas is now free from all noxious properties. Until recently, the quality of the gas made in London was very inferior, and consequently it is not yet generally used there in private houses; but by employing a better kind of coal and other means, the quality has of late improved, and its use may be expected to extend. As it is, the capital of the numerous gas-works in London amounts to £3,000,000, and the daily consumption of coal exceeds 1000 tons.

The use of gas-lighting in cities and towns is now pretty general over the world. Where coal is scarce, it is prepared from resin, oil, refuse fats, soap-water, &c. Oil-gas was at one time extensively used in Great Britain, but though it is of very superior quality, the comparative economy of coal-gas made the manufacture be given up.

The gas prepared from coal is neither a simple nor a single gas; it is a very variable mixture, chiefly composed of two inflammable gases, commonly known by the terms, heavy carburetted hydrogen, or olefiant gas, and light carburetted hydrogen. Both these gases are compounded of hydrogen and charcoal in definite proportions. The first—namely, olefiant gas—is composed of 2 atoms of hydrogen with 2 atoms of charcoal; or by weight, 2 hydrogen to 12 charcoal. Its specific gravity is ·9722, common air being considered as unity, or 1·000. When pure, it has no taste, and scarcely any smell; it burns with a dense white light, combining with three times its bulk of oxygen.

The second—namely, light carburetted hydrogen—is composed of 2 atoms of hydrogen, combined with 1 atom of charcoal; or by weight, 2 hydrogen to 6 charcoal. Its specific gravity is ·5555. It is this gas which is met with in coal-mines. According to the experiments of Sir Humphry Davy, it forms explosive mixtures with air when the latter is mixed with it in any proportion between 5 and 14 times its bulk; it burns with a yellowish flame, combining with twice its bulk of oxygen.

Other gases enter into the composition of coal-gas, though in smaller proportions; thus hydrogen, carbonic oxide, and nitrogen, are uniformly present; it also contains certain other compounds of hydrogen and charcoal in a state of vapour. To these last, in which the proportion of charcoal is very high, both the smell and a considerable increase in the luminous property are attributed.

The relative proportions of the different ingredients in coal-gas are ever varying, being dependent upon the quality of the coal from which it is made, and to a considerable extent upon the methods employed in its preparation; and, as may be supposed, it must vary also in its specific gravity and luminous quality. When it is made in the best manner from good coal, the specific gravity is sometimes as high as ·750; in other circumstances, it is as low as ·400, or even lower. The former specific gravity indicates with tolerable certainty a large proportion of olefiant gas; the latter, a superabundance of light carburetted hydrogen and hydrogen. And as the amount of light evolved by combustion depends greatly upon the quantity of olefiant gas, which has a high specific gravity, the specific gravity of any specimen of coal-gas may be taken as a pretty correct indication of its actual illuminating value.

The presence of hydrogen and carbonic oxide deteriorates the gas by diluting it; but when once produced, they cannot be removed. Carbonic acid and sulphuretted hydrogen are impurities which the manufacturer ought to separate. It is to the presence of sulphuretted hydrogen that the tarnishing effect of bad gas upon paintings, silver plate, &c., is to be ascribed.

Manufacture of Gas.

The best coal for gas-making is that which is called *cannel*, or parrot. Of the cannels, the famous Boghead coal, or Torbanehill mineral, stands highest. A ton of this mineral yields 15,000 cubic feet of gas, of the specific gravity of ·752; while a ton of Newcastle coal yields 10–12,000 feet, specific gravity ·4–·500; and some other English coals, 8–10,000 feet, of specific gravity as low sometimes as ·320.

An average specimen of Newcastle coal, for example, consists of 82·12 per cent. of carbon, 5·31 of hydrogen, 1·35 nitrogen, 1·24 sulphur, 5·69 oxygen, 3·77 ash or earthy matter. When the coal is exposed to a high temperature, a certain proportion, varying from 70 per cent. in Boghead coal to as low as 20–30, is volatilised, while the rest remains as coke, composed chiefly of carbon and earthy matter. The volatilised ingredients enter into a new series of combinations, giving rise not only to coal-gas, but at the same time to a variety of other products—namely, water, tar, naphtha, carbonate and sulphate of ammonia, carbonic acid, and sulphuretted hydrogen. The essential parts of the apparatus, by which the coal is distilled and the last-named substances separated from the gas proper, are rudely sketched in the annexed cut.

A represents the retort, of which several are commonly in use at once. It is a cylindrical, elliptical, or D-shaped vessel of clay or cast iron, of 6–9 feet in length, and 12–20 inches internal diameter. It is built horizontally into a furnace, in such a way that the fire

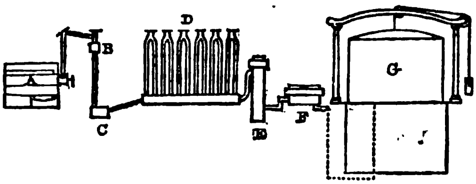

Fig. 19.

can act completely around it. The retort has two openings, both external to the building: one of them is the end of the cylinder, which is furnished with a closely fitting lid of iron; the other is an aperture in its upper surface for the exit-pipe, which passes from the retort to B, a vertical section of the hydraulic main, which is a round or square vessel of iron, passing above and in front of the whole line of retorts. It is half filled with liquid, into which the exit-pipe dips; it serves to collect the gas and other matters from any number of retorts, and to cut off its escape by any retort which may be open. It is connected by means of a wide pipe with C, the tar-cistern, in which the tar and everything deposited from the gas by cooling is collected. From the tar-vessel, a tube rises in a sloping direction to D, the condenser—a series of tubes through which the gas is made to pass, that it may be thoroughly cooled. To the condenser there is sometimes attached E, an upright cylindrical vessel filled with brushwood or dry coke, through which the gas passes before it is sent to F, the chemical purifier. There are usually several vessels of this kind, and of various forms: they contain quicklime, either dry or mixed with water to the consistence of cream. From the purifier, a tube passes to the bottom of the tank in which G, the gas-holder, or the gasometer, as it is improperly called, is suspended.

The retort being heated to a red heat, the charge of coal, about 200 pounds or upwards, is quickly shovelled in, and immediately gives off dense smoke and flames. The mouth of the retort is now closed by its lid, which extinguishes the flame by shutting off the air, and leaves no outlet for the dense vapours arising from the coal, except by the exit-pipe; they rush through this tube, and are heard bubbling up into the hydraulic main until the charge is exhausted.

It is of importance, in this part of the process, to attend to the temperature of the retort; for if it is too hot, some of the heavy gas will be decomposed, depositing part of its carbon, and forming light carburetted hydrogen; if, on the contrary, it is not of a certain temperature, there will be formed a large proportion of tar, and the gas will be light and of bad quality. It is also essential to draw the charge before it is quite exhausted, as the last portions of gas consist chiefly of hydrogen and carbonic oxide, both of which, as already stated, have a most injurious effect upon the quality of the whole product.

The dense vapours which pass from the retort into the hydraulic main consist of coal-gas mixed with tar, water, naphtha, salts of ammonia, carbonic acid, sulphuretted hydrogen, &c. Being subjected to a process of cooling in all parts of the apparatus as far as the brushwood box, the impurities are condensed, with the exception of the carbonic acid and sulphuretted hydrogen; and from the sloping or descending direction of the apparatus to the tar-cistern, they collect in it, and are pumped off as occasion requires. The gaseous matter still retains particles of tar mechanically mixed with it, from which it is freed by being forced through the *scrubber*, E. It is now made to enter the chemical purifiers, where it is either washed by agitation with a mixture of quicklime and water, or is passed through a succession of trays covered with thin layers of this substance in a slightly moistened state. In this process the lime combines with the sulphuretted hydrogen and carbonic acid, forming hydrosulphuret and carbonate of lime, which, being both solid, are retained; and the gas, now purified, is passed into the gasometer, where it is stored for nightly consumption.

Various improvements are every year being effected in the manufacture of gas—these modifications having reference chiefly to the retorts, the purifying apparatus, and the separation of the impurities, so as to render them available in some of the useful arts. Thus, clay and iron retorts of various shapes are now used; ammonia is separated by using alum, green vitriol, or dilute sulphuric acid, and is used as a valuable manure; gasometers are also variously constructed; the tar is economically employed as fuel or in the preparation of naphtha; and this naphtha is used either as a solvent, as an independent source of light, or in the impregnation of coal-gas, whereby its illuminating power is vastly increased.

Distribution of Gas.

The distribution of the gas from the gasometer to its places of consumption is effected in cast-iron pipes called *mains*, the size of which, in each case, it is the business of the engineer to determine. The pipes branching from the mains to supply gas to dwelling-houses or manufactories are called *service-pipes*, which, within doors, consist of small tin tubes.

Throughout all the ramifications of the fittings, the pipes have, or should have, an inclination to the main, and the main itself should incline towards the gas-work. The necessity for this arrangement arises from the presence of watery vapour in small quantity in the gas; being condensed into water in the pipes, it naturally collects in the lowest part, and at last interrupts the continuous flow of gas, so as to cause a flickering of the flame in the burners. Where the proper inclination of the pipes cannot be attained, this is obviated by placing a stop-cock and pipe at the part where liquid is apt to collect, so that it can be let off from time to time as it accumulates. An error in this respect in laying the service-pipes of a house, is a frequent source of domestic discomfort.

The quantity of gas charged for by gas-companies was at one time regulated by the number and kind of burners employed, and the time they were allowed to burn; but this was everywhere found to be a most uncertain and unsatisfactory method of guessing the consumption by any individual. It is now obviated by the use of a very simple and ingenious instrument invented by Mr Clegg, and subsequently improved by Mr Crossley; it is called the *gas-meter*, and consists of a hollow case of

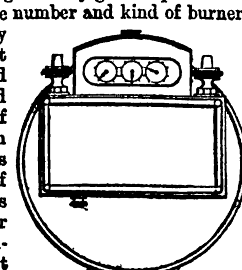

Fig. 20.

iron, containing an inner cylinder or drum, so constructed, that the gas passing through it, by the pressure it receives at the gas-work, causes it to revolve on an axis; each revolution allows a known quantity of gas to pass through the water, with which the outer vessel is partially filled, to the exit-pipe; and as the revolutions are registered by wheel-work and an index, the quantity of gas consumed is indicated with considerable accuracy. It is usually examined quarterly by a person employed by the gas-company, who charges the consumer according to the quantity indicated. The imperfections of this form of gas-meter are, that it is liable to have the water

frozen in severe weather, and that fraudulent consumers often tamper with the apparatus. To remedy this, various 'dry meters' have been contrived, but none have yet come into general use.

Regulators or Governors.—When other lights in the same premises have been put out, the gas that supplies these burners increases the pressure in the pipes, and is diffused over the other lights in the premises; and if not checked, there will be comparatively little reduction in the expenditure, although one-fifth of the lights are extinguished. To obviate these inconveniences, instruments called *governors* or *regulators* have been constructed, on the principle of making the pressure of the gas regulate the size of the opening through which it passes. The adjoining wood-cut represents a regulator invented by Messrs J. Milne and Son, which has been found to answer well in the premises where this sheet is printed. It can be readily placed upon any service-pipe, and being adjusted to the pressure required, it gives a regular flame and expenditure of gas, notwithstanding any variation of pressure in the main.

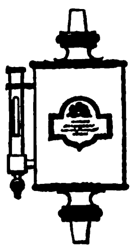

Fig. 21.

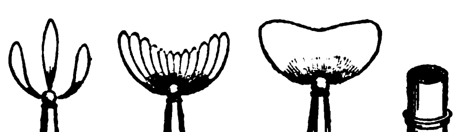
Burning of Gas.

From what has been said of the nature of flame, it will be readily understood that the manner in which gas is burnt may actually have an effect upon the amount of light derivable from a given quantity. It is found by experiment, that a properly constructed argand burner gives more light than can be obtained from the same quantity of gas by any other method of burning. In the argand, the flame is steadied and the current of air increased by the use of a glass chimney, which sensibly diminishes the size of the flame, at the same time increasing its brilliancy.

Other burners in common use are known by the names—single jet, cockspur, union-jet or fan, fish-tail, and bat-wing. In the single jet, the gas issues from a single aperture; in the cockspur (*a*), from three apertures, as shewn in the figure; in the union-jet (*b*), from a series of small holes, so that all the jets may unite laterally; in the bat-wing (*c*), from a slit instead of a



a *b* *c* *d*

Fig. 22.

series of holes; in the fish-tail, by making two jets cross each other, and yet issue from the same hole; and in the argand (*d*), from a circle of small holes, the centre of which is an open space for the admission of air. The relative quantity of light which they yield from the combustion of similar quantities of gas is thus given by Dr Fyfe: namely, single jet, 100; fish-tail, 140; bat-wing, 160; argand, 180. A high flame gives more light, with the same quantity of gas, than a low.

If the flame smokes in an argand, it is evident that some adjustment is necessary, and the gas should either be lowered or the chimney contracted, until it gives a clear cylindrical flame of three or four inches in height. In the fish-tail burner, if the flame flares, or makes a noise in burning, the gas should also be lowered; but to diminish either much below these points, does not effect a saving of gas in proportion to the diminution of light. Hence the important conclusion, that it is more economical when the light is too strong to procure a smaller kind of burner, or where several lights are used, to put out some of them altogether, than to lower the flame in the whole.

Bude Burner—Bude Light.—The Bude burner, so called from the name of the residence of its inventor, Mr Gurney, consists of two, three, or more concentric argand burners, each inner one rising a little above the outer. On the same principle, a powerful light is produced by a number of flat flames disposed in concentric circles like the petals of a rose. The *Bude Light*, also the invention of Mr Gurney, depends upon introducing oxygen into the centre of the flame, instead of air, as in the common argand. A light of the most dazzling brilliancy is thus produced. The House of Commons is lighted by this means, the brilliancy being softened by the intervention of a ceiling of ground-glass.

The *Lime-ball Light*, another of Mr Gurney's discoveries, though sometimes called the *Drummond Light*, is produced by directing the flame of a mixture of oxygen and hydrogen, against a piece of lime. The flame is itself pale, but the intense heat it communicates to the lime makes the latter give out a light rivalling that of the sun. The lime remains unaltered, shewing that a luminous body need not be combustible.

Comparative Cost of Gas-light.—Various calculations of the relative expense of gas-light, compared with other lights, have been made. Thus, when tallow-candles are 9d. per pound, wax-candles three times the price of tallow, train-oil 2s. per gallon, and coal-gas 9s. per 1000 cubic feet, it is computed that the relative expense will be as under—namely,

Wax, . .	100	Oil, . .	5
Tallow, . .	25	Coal-gas, . .	3

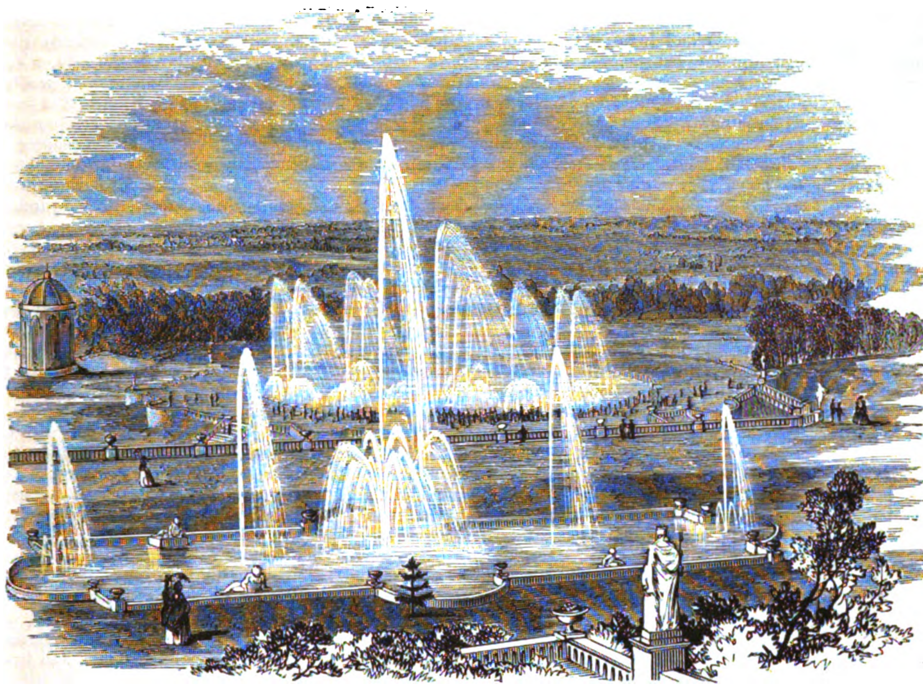
According to another calculation, 'when gas is at 4s. 6d. per 1000 feet, and dip-candles 7d. per pound, the cost of an equal amount of light from the two sources will be as 4s. 6d. to £1, 10s. 10d.'

Many individuals, who complain that the adoption of gas-light has proved no saving to them, will be surprised at the above statements. They will find, however, on examination, that they now light up their houses far more brilliantly than they were accustomed to do when candles or oil-lamps were in use, and that their equal expenditure is thus accounted for.

Naphthalised Gas.—When gas is passed through naphtha, it becomes saturated with naphtha vapour, which, being exceedingly rich in carbon, greatly increases the illuminating power of the gas. Apprehension of danger from the inflammability of the substance is perhaps the cause that this improvement is not generally adopted. It may be simply applied by making the gas, before reaching the burners, pass through a box containing a sponge saturated with naphtha.

Hydro-carbon Gas.—When steam is passed over red-hot coke, it is decomposed, its oxygen uniting with the carbon to form carbonic acid and carbonic oxide, and its hydrogen being set free. The mixture of gases thus generated, called water-gas, is inflammable, but scarcely at all luminous. It is therefore passed through a retort in which tar, resin, Boghead mineral, or other substance producing heavy hydro-carbons, is distilling, and thus receives the necessary amount of carbon. This new illuminating gas has numerous advocates, and is used in various localities; but it is still a question, whether the hydro-carbons necessary to mix with the water-gas, would not be an equally good source of light alone.

The employment of gas at a distance from towns, is limited by the expense of the apparatus as compared with the quantity of light required; but where the annual expenditure for light is not less than £40, it is probable that gas might be made with advantage. Gas made from oil or resin, owing to the comparative simplicity of the apparatus, is likely, on a very small scale, to be more economical than coal-gas.



SUPPLY OF WATER—BATHS—DRAINAGE.

AMONG the complicated arrangements of civilised life, few are of higher importance than those which relate to the command of water. Whether for dietetic and domestic purposes, for the bath, or for carrying away the corrupting refuse of our towns and cities, a liberal supply of good and wholesome water is an indispensable requisite. Admitting the necessity, we intend in the following pages to give some account of the water-supply, baths, sewers, and other sanitary provisions depending on this element, both in ancient and modern times—dwelling on what seems more especially applicable to the wants of our own populous localities.

SUPPLY OF WATER.

Water is one of the primary wants of human life, no less essential than air and food; it is, besides, peculiarly delightful to the senses generally, and a source of endless convenience; hence the strong and religious interest that has always been attached to the means of its supply. In the earliest records of civilisation, we read of the digging of wells, and of quarrels about the possession of them. The 'Pools of Solomon,' near Bethlehem, which remain now almost as perfect as when they were built, were connected with a scheme for supplying Jerusalem with water. In Assyria and Persia, from the earliest times, water has been conveyed to towns from astonishing distances in open channels or canals, and in subterranean tunnels or *kanats*. In Egypt also, and in China, gigantic works for conveying water, both for domestic use and for irrigation, have been in existence from remote antiquity. Nor were these undertakings confined to the eastern hemisphere; we have evidence of the existence of kindred works in pre-Christian America. The ancient city of Mexico, which was built on several islands near the shore of the lake, was connected with the mainland by four great causeways or dikes, the remains of which still exist. One of these supported the wooden aqueduct of Chapoltepec, which was constructed by Montezuma, and destroyed by the Spaniards when they besieged the city. Hydraulic works on a great scale had also been executed by the Incas of Peru.

AQUEDUCTS.

Of all the ancient nations, the Romans paid the greatest attention to the supply of water, and carried the construction of *aqueducts* to the greatest perfection and magnificence. In the original sense of the word (*aquæ ductus*, a duct or conductor of water), every leader or channel of water would be an aqueduct; but the term is used to signify specially a channel cut through mountains, and borne on arches across valleys, so as to convey water by a gradual descent all the way from its source to the place where it is wanted.

Rome at first depended upon water drawn from the Tiber and from wells; it was to Appius Claudius, about 312 years before the Christian era, that the Romans were indebted for the improvement of bringing superior water from a distance by means of aqueducts, and for several centuries after his time, additional works were constructed, as the necessities and luxuries of the city demanded. The *Aqua Appia* was only eleven miles long, but some of the subsequent ones were about sixty miles: that built by Claudius was forty-six miles, of which nine and a half were on arches; and it discharged 97,000,000 gallons in twenty-four hours. One of these aqueducts was formed of two channels, one above the other; the most elevated being supplied by the waters of the Tiverone (Anio Novus), and the lower one by the Claudian water. It is represented by Pliny as the most beautiful of all that had been built for the use of Rome. The Aqua Marcia, Aqua Julia, and Aqua Tepula, entered Rome by one and the same aqueduct, divided into three ranges or stories, each of which supported its own independent channel-way.

In general, the conduits, or water-courses, were built of stone, rough or hewn, occasionally of bricks, and in either case cemented by the finest tempered mortar. Some were of a square form, paved, and covered with flagstone or tiles; others were arched over, as shewn in the accompanying cut; and some were throughout of an elliptical form. This conduit, or stone-pipe (*c*), if we may apply such a term, was conveyed through hills by tunnels, and across valleys upon single arcades, or even upon double and triple tiers of arches. In general, these arches supported only one water-course; but occasionally each tier had its own conduit, so that an aqueduct presented a double or triple form. Having arrived at their destination, the waters were generally received in reservoirs, and conducted by leaden pipes, or by stone grooves, into private cisterns, or dispersed throughout the cities by means of public fountains, which were often adorned with all the magnificence and allegorical allusion of ancient architecture. These structures were under the charge of a public functionary; and it is from the treatise of Sextus Julius Frontinus, who was inspector of the aqueducts of Rome under the Emperor Nerva, that we derive most of our information respecting the water-works of the imperial city.

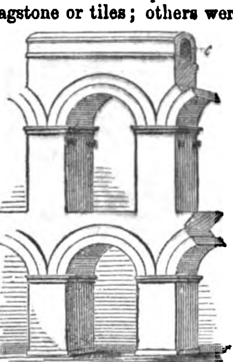


Fig. 1.

About 100 A. D. there were nine aqueducts, which, 'it has been calculated, furnished Rome with a supply of water equal to that carried down by a river thirty feet broad by six deep, and flowing at the rate of thirty inches a second.' (*Smith's Dictionary of Greek and Roman Antiquities.*) Another calculation makes the daily supply 300,000,000 gallons. The number of aqueducts was subsequently augmented to fourteen. Three of them are still serviceable, and modern Rome is more copiously supplied, perhaps, than any other city.

The system of aqueducts was also introduced into those countries that owed allegiance to the mistress of the world; in Greece, Italy, Spain, and Gaul, many were erected. That at Nimes was perhaps the oldest of these provincial aqueducts; it traversed a most diversified district, piercing hills and crossing valleys. At the place where it crosses the Gardon, it is termed the Pont du Gard; it is 300 yards in length, and is composed of three ranges of arches, one above the other, to the height of 160 feet.

Of the use of the aqueduct in recent times, two instances are alone worthy of notice—the *Lisbon* and the *Croton* at New York. The former, completed in 1738, is about three leagues in length; near the city, it is carried over a deep valley for a length of 2400 feet, by a number of bold arches, the largest of which has a height of 250 feet and a span of 115. The Croton Aqueduct, which conveys the waters of the Croton river for a distance of thirty-eight miles to the city of New York, is one of the greatest undertakings of modern times. It was commenced in 1837, and finished in 1842, and is calculated to discharge upwards of 60,000,000 gallons in twenty-four hours! The united supply of the ten London water-companies is stated at 81,000,000 gallons daily. The interior of the aqueduct is throughout of an arched or elliptical form, founded upon hydraulic concrete, built of square stones, and finally lined with brick prepared for the purpose. As the magnificence of aqueducts depends upon the height and number of arches requisite to carry them across valleys, it may give some idea of that under consideration, when it is stated that Haarlem River is crossed by fifteen arches, seven of which are of 50 feet span, and eight of 80 feet, the greatest height being 150 feet from the foundation to the top of the mason-work. No essential change occurs in the form of the channel-way from the fountain reservoir on the Croton, to the receiving reservoir on the island of New York—a distance of thirty-eight miles—except in crossing Haarlem River, to reach the island, and in passing a deep valley on the island, where iron pipes are used instead of masonry, to provide for the pressure consequent upon a depression from the regular plane. Thus the course of this artificial stream may be said to combine two principles—that of the ancient aqueduct, and a descent and ascent, as in ordinary pipes.

The water is first received in a reservoir covering thirty acres, and containing a month's supply; and from this it is conducted two miles further, to the distributing reservoir, which is 115 feet above the level of the tide. The whole cost of the work was about 9,000,000 dollars; and adding to this the cost of pipes, and arrangements for distributing the water in the city, it will make the total cost for supplying New York with water about 12,000,000 dollars.

Compared with the hydraulic works of the Romans, it must be confessed that the efforts made to supply modern cities, in Europe at least, are insignificant enough. It is only since the beginning of the sanitary movement, occasioned by the repeated visitations of cholera since 1832, that the subject of water-supply has at last occupied public attention. The result of every inquiry and every day's experience, has been to bring out more strongly the decided effects on the health of a community arising from the quantity and quality of the water at their command. Nor is the subject less important as regards refinement of taste and manners. Without abundance of water, there cannot be cleanliness; and the connection between physical and moral purity has been long felt and acknowledged. The chief points of interest on this subject may be arranged under the heads of the Sources of Supply, the Qualities of Water, and the Arrangements for its Distribution.

SOURCES OF WATER.

The great reservoirs of the globe are the oceans and seas. The water, however, as it there exists, is unfit for most purposes, on account of the large amount of other matters dissolved in it. The principal foreign ingredient is sea-salt, besides which it contains, in considerable amount, salts of lime and magnesia, along with iodine and bromine. But the process of evaporation or distillation constantly going on over the whole liquid surface of our planet, yields to the atmosphere a supply of pure water in the shape of vapour; and this descending in rain, forms the ultimate source of all *fresh* water, as opposed to the salt water of the ocean. It presents

itself chiefly in the forms of surface-water, rivers, and springs.

Surface-collection.—Rain-water, as it is formed in the upper regions of the atmosphere, is the purest that nature supplies; but in descending, it brings with it whatever impurities are floating near the surface, which, in the neighbourhood of towns, are numerous, consisting of various gases, together with soot and other floating particles, organic and inorganic. Rain-water has a strong affinity for organic impurities—that is, the corrupting ingredients derived from vegetable and animal bodies, and which are diffused over every surface in the vicinity of living beings; hence, when collected from the roofs of houses, it has a tendency to rapid putrefaction. Being free from saline ingredients, it is excellent for washing, but is not generally pleasant to drink.

But if we resort to a barren district of rock or sand, destitute of vegetation, and remote from the pollution of towns, we may obtain water such, that comparatively little organic impurity has entered into its composition. Notwithstanding several defects, it happens in various places that a surface-supply is the best that can be had, and is, on the whole, satisfactory.

Rivers.—The water obtained from running streams is in part what has flowed immediately from the surface, and in part the water of springs, shallow or deep. In any case, a considerable amount of contact with the ground has taken place, and in consequence saline matter is liable to be dissolved in a greater or less degree. The extent of the impregnation, as well as the kind of material dissolved, will depend on the rocks and strata of the river basin. Water flowing from granite rock, as the river Dee in Aberdeenshire, has a very small quantity of dissolved salts. Slate formations are also favourable to the purity of the water flowing over them. Sandstone is very inferior in this respect; while the limestone and chalk covering large districts of the country, impart a nearly constant amount of lime-salt to all the running streams. The lime is not unfrequently accompanied by magnesia.

River-waters, besides the qualities they derive from their primitive sources, are apt to contain mud and other matters in suspension, and are thus deficient in the clearness and transparency so essential to the satisfaction of the eye in a drinking water. The agitation which a running river undergoes prevents stagnation and such decay of organic matter, accompanied by an offensive smell, as occurs in canals; but it also deprives the water of some air and free carbonic acid, which renders it, according to the opinion of many, less fresh to the taste. Moreover, the water partakes of the extremes of summer and winter temperature, and in the hot months can hardly be free from organic impurities and insects. But, on the other hand, the supply from one of our large rivers is boundless and unfailing; and it conveys the surface-drainage and spring effusions of a large tract of country, without incurring any trouble or expense as to the original sources. With far more of mineral impurity than surface-water, river-water will usually present less of vegetable and animal impurity, in consequence of the tendency of the mineral impurity to increase, while the organic impurities diminish, by time and exposure.

Springs.—When water falling on the surface of the ground sinks into the soil, descending downward by slow percolation till it encounters an impervious bottom, and rises up at some convenient opening by the force of hydrostatic pressure, the outgush is called a spring. The conditions necessary to the occurrence of springs are —1*st*, The rain falling on the higher grounds must find admission into the interior to some considerable depth; 2*d*, By the force of the pressure from above, it must pass in lateral directions—in other words, it must find pervious beds or openings right and left; 3*d*, It must become hemmed in above by some stratum that does not give an easy passage, and therefore concentrates the pressure on the places where openings occur; and 4*th*, In the lower grounds where it has descended beneath an obstructing bed, there must be interruptions, fissures, or pervious strata, whereby it can rise to the surface again. Mountain districts, and a varied and irregular stratification of alternating pervious and impervious layers, are favourable to the concentration of water and its discharge in the form of springs; while, on the other hand, flat regions and uniform coverings of sand and gravel render springs impossible.

The slow percolation through the interstices of a gravelly layer, or the crevices of rocks, is the cause of the mineral impurities which distinguish the water of springs. At the same time, this slow action most effectually rids the water of any organic impurities contracted at the surface. Air, too, is largely taken in by compression along with the saline matter of the rocks, and the temperature of the interior is imparted to the whole mass; whence it happens that springs of moderate depth represent the average temperature of a climate. Very deep springs are of a higher temperature. The qualities that recommend water to the eye and to the palate belong in a pre-eminent degree to spring-water: it is clear, sparkling, and cool, and is totally free from the offensive taint so common in all other waters, as well as devoid of the animalcules generated by organic impurity.

QUALITY OF WATER.

Perfectly pure water is hardly to be found; rain-water, and even artificially distilled water, are only approximates. The impurities of water exist in one of two ways—either floating suspended in the form of solid particles, or in a state of solution. In the one case, there is a mechanical mixture; in the other, a sort of chemical union. The chief impurities may be considered under the heads of Mineral Matter in Suspension, Mineral Matter in Solution, and Organic Matter.

Mineral Matter in Suspension.—When running water comes upon a loose bottom, it carries the finer particles of sand and earth along with it, and the quicker its flow, the larger the pieces that it can keep afloat. If the water comes into a position of perfect stillness, the matters thus floated gradually sink to the bottom again —the heaviest first, and the others in succession. The particles gathered from beds of clay are the most difficult to separate from water by mere subsidence; either they are in a state of greater fineness than particles of lime, silica, or other minerals, or else the water has a more than ordinary adhesiveness to the material of clay. Whatever be the reason, the agitation of water in contact with a clay surface imparts a drab or rhubarb colour, arising from the diffusion of fine solid particles; and matter of such consistence is, for all practical purposes, incapable of being satisfactorily separated either by subsidence or filtration. Besides earthy matter, compounds of iron and lead are also in some circumstances present in a solid state, and may be got rid of by filtering.

To separate clay-powder from water, the practice has long been resorted to in India and China of putting in a piece of alum, which seems to act by the property it has of curdling some organic substances, and of causing others to adhere as dyes to such solid matters as may happen to be in the water. This is the oldest known device for purifying water by anything approaching to a chemical process.

Dissolved Mineral Matter.—Spring-water, which is generally clear and sparkling, holding no solid matter in suspension, is seldom without a large amount of dissolved mineral matter, sometimes as much as 2 parts in 1000, commonly from 1 in 1000 to 1 in 20,000. River and surface water also contains more or less dissolved minerals.

The great bulk of the solid matter held in solution in ordinary waters consists of salts; that is, combinations of acids with various bases (see CHEMISTRY). The saline bases are chiefly soda, potash, lime, and magnesia. The most material are the salts of lime and magnesia, as

they are the causes of what is called 'hardness' in water, which we shall speak of more particularly afterwards. The most important salt of lime is the *bicarbonate*, which is derived from chalk or limestone. Chalk or limestone is a *carbonate* of lime—that is, a compound of lime with one equivalent of carbonic acid—and is almost insoluble in water; but when water containing an excess of carbonic acid—as is the case with spring-water especially—passes over limestone, it gives it a double dose of carbonic acid, and converts it into bicarbonate, which is soluble. The waters having bicarbonate of lime for their chief impurity, are familiarly spoken of as the chalk-waters.

The other salt of lime often present in water, is the *sulphate* or *gypsum*. The important distinction between the bicarbonate and the sulphate lies in the fact, that the first, the bicarbonate, may be in great part precipitated, or thrown down in a solid form, by boiling; whereas the second, the sulphate, cannot be so precipitated.

Apart from its hardness, it has been made a question whether water containing salts of lime is injurious or not to the human constitution. The defenders of the hard water at present supplied to the metropolis even go the length of maintaining that salts of lime are necessary in the drink of animals, in order to supply the lime of the bones, and that it would be prejudicial to remove it. But the lime present in the bones of animals is found in abundance in their ordinary food; and the best answer to the argument is, that the inhabitants of many large cities—such as Aberdeen and Manchester—habitually drink water almost entirely destitute of lime, and yet shew no appearance of deficiency of bone. Dr Lankester holds that there is evidence to prove that carbonate of lime in large quantity is positively injurious; and most physiologists are agreed that pure water is the best for securing the health of animals and man. The lower animals give a marked preference to soft water, and thrive better on it; the horse will leave the clear spring, and go to the muddy pond.

With regard to magnesia, its salts are well known to act as powerful medicines when taken in large doses, and it may be presumed are not altogether without effect in the small quantities existing in ordinary magnesian waters. A foreign physician has lately made the observation, that magnesia is the characteristic ingredient of waters in the districts where the diseases called *cretinism* and *goitre* abound.

Of salts of *soda* and *potash*, the principal is common salt, or the muriate of soda. Sulphate of soda (Glauber's salt) occurs along with the muriate in the salt-springs of watering-places as well as in the sea-waters. None of all these salts have any effect on the hardness. In the case of sea-water, which is very hard, the effect is not due to common salt, but to the lime and magnesian salts dissolved in it; were it not for these, sea-water would be perfectly suitable for washing, although not for drinking. The Artesian-well water of London contains a large amount of alkaline salts, chiefly of soda; in one case, as much as 42 grains a gallon. Such water is extremely soft for washing purposes, and well adapted for cookery; but it is doubtful if so great an amount of alkali habitually imbibed be not injurious to the bodily system.

Salts of *iron* in considerable quantity make what are technically named *chalybeate* waters, which belong to the medicinal class. When the iron exists in the spring as carbonate, which is the most usual case, on exposure to the air, it is changed into the peroxide, and falls down in the form of an ochery precipitate. Salts of iron give an inky taste to the water, and a yellowish tint to linen washed in it.

Hardness in Water.

The quality of hardness in water is commonly recognised by the difficulty experienced in washing, and by the amount of soap necessary to form a lather. This quality is injurious also in the preparation of food; but its action is most universally felt in washing operations. It occasions an enormous waste of soap, an extra labour, and a corresponding tear and wear of clothes. The hardening matter contained in 100 gallons of spring-water, drawn from wells or borings in the chalk-strata, will destroy thirty-five ounces of soap—that is, the first thirty-five ounces of soap added to this quantity of the water will disappear without forming any lather, or having any cleansing effect. Soap is a compound, formed of an alkali (soda or potash) joined to an oily acid. (See CHEMISTRY APPLIED TO THE ARTS.) When a salt of lime, then, is present in the water, the lime decomposes the soap, and combines with the oily acid to form a lime-soap, which is insoluble, and has no detergent properties.

The most usual hardening ingredients are the salts of lime. Every lime-salt whatsoever hardens water and destroys soap in proportion to the lime present. Salts of magnesia are hardening salts, but not in a regular proportion to the quantity, there being some irregularities in their action. When a magnesia-salt is present along with a lime-salt, the magnesia acts rather as a curdler of the soap than as a destroyer. Salts of iron also produce hardness. Salts of soda and potash have no hardening effect.

Dr Clark, Professor of Chemistry in Marischal College, Aberdeen, has devised a scale of hardness which is now universally employed in the chemical description of waters. The hardening effect that would be produced by one grain of chalk dissolved in a gallon of water is one degree of hardness; in like manner, four grains per gallon would produce four degrees of hardness; ten grains, ten degrees; and so on. The degrees are expressed in numbers—thus, 1°, 4°, 10°, 15°, are one, four, ten, fifteen degrees respectively.

The scale of hardness increases with the consumption of soap requisite to form a lather. Professor Clark has made use of this fact in his process of testing for hardness—a process of extreme delicacy. It consists in the employment of a solution of soap of measured strength; and according to the quantity of solution requisite to form a lather of a certain duration, is the hardness of the water. By this test the value of a water for washing, and for all other purposes where hardening matter is an objection, can be determined with great ease, and with a precision scarcely equalled by any process in chemistry. The employment of the definite scale of hardness, and of the soap-test for measuring its amount, has tended more than any other circumstance to facilitate the determination of proper waters for the supply of towns.

Next to washing, the deleterious consequences of hardness are felt in various culinary operations, and especially in the infusion of tea. It is a fact of universal experience that hard water is unfit for tea. In experimenting with a series of waters at 4°, 8°, 12°, 16° of hardness, Professor Clark found that the difference of strength of the infusions, as manifested by the depth of colour, was evident at once to the eye, the softest water giving the greatest depth of colour. As the hardness of the water increased, the infusion was less transparent too, as well as weaker; and above 16°, it was disgustingly muddy. 'The only way,' he states, 'of making an infusion of tea with waters at 8°, 12°, or 16°, equally strong with an infusion by water at 4°, is to increase in each case materially the quantity of tea infused. Sub-carbonate of soda in crystals may be made use of in very small quantities in order to soften the water, and make it fitter for the purpose of infusing tea; it produces this effect by decomposing the earthy salts present; but if made use of in any proportion beyond what will exactly decompose the earthy salts present, the excess may indeed deepen the colour of the infusion—by dissolving some coloured vegetable extract, such as pure water would not dissolve—but it

will infallibly injure the fine flavour of the tea to all persons not accustomed to the taste of soda in their tea.'

According to M. Soyer—who was requested by the General Board of Health to try the effects of hard and soft water in cooking, and was provided with solutions of known hardness for that purpose—the operation of hard water is prejudicial both to meat and vegetables.

From the experiments on tea, already referred to, it would appear that when water approaches to 8° of hardness, it begins to be decidedly unfavourable to the infusion. It may be stated generally, that for the purposes of washing and cooking, a water of less than 6° is soft, but above this point the hardness becomes objectionable. At 8°, the water is moderately hard; at 12°, it is very hard; at 16°, the hardness is excessive; and much above this, it is intolerable.

To make these observations more intelligible, we may mention a few instances of known waters, with their place in the scale. In Keswick, the water of the new water-works there constructing is under half a degree of hardness; in Lancaster, it is 1½°; and in Manchester, 2°. The water of the Dee at Aberdeen, which is used for the supply of the town, is 1¼° of hardness. The river Clyde, supplying Glasgow, is 4½°, and may also be reckoned a soft water. The Thames at London, as well as the New River, is about 13°, while many of the tributaries of the Thames rise as high as 16°; but being all chalk-waters, they may be materially softened by boiling. Springs from the chalk commonly range from 16° to 18°; but particular springs are to be met with in some parts of the world four or five times as hard, from the presence of bicarbonate of lime. The water of the Treasury pump in London has from 50° to 60° of hardness. In many parts of the continent, hard waters abound; but the testing of waters has not been so much attended to there as in this country.

From an extensive examination of the waters of England and Wales, made by the General Board of Health, it appears that in England the hardness of springs in general is excessive (average 25°·86); that a very large number of rivers have an injurious and exceptionable amount of hardness (13°·05); and that surface-waters may be collected in a state that is to be considered soft (4°·94).

Lead in Water.

Injurious effects have frequently arisen from the contamination of water with lead, derived from leaden pipes and cisterns. Some kinds of water are known to act powerfully on a leaden surface, and others scarcely at all; but the qualities and circumstances on which the action depends have never been satisfactorily determined. Distilled water, and soft waters in general, act most decidedly, but by no means in proportion to their softness. It has been very generally held that the presence of free carbonic acid was the cause; but according to some recent experiments made by Dr Clark, distilled water, from which carbonic acid is carefully excluded, has still a very marked action on sheet-lead. The presence of air in the water seems one essential condition; light also increases the action. The saline matter present in hard water has been believed to hinder its impregnation by lead; but this opinion is set aside by the fact, that chalk spring-water, after softening by Clark's process, has no action on lead.

The presence of vegetable matter would seem to have more to do with it. Dr Clark finds that by adding a little vegetable matter—as a bit of raw potato—to the softened water, the action becomes decided; and it has been observed that when leaves drop by chance into a lead cistern, the spots where they lie become visibly corroded. On the other hand, it has been found that water coloured by peaty matter has less action than when clear, probably because water so impregnated usually contains very little air.

The water of Loch Katrine, from which Glasgow is to be supplied by the Corporation Water-works, now constructing, is of remarkable purity, having only two grains of solid matter of all kinds in the gallon, and about one degree of hardness. According to extensive sets of experiments by distinguished chemists, this water is allowed to have an intense action* on lead under certain circumstances—namely, '1*st*, If the lead be bright and highly polished; and 2*d*, If the lead and water be freely exposed to the access of air.' But it 'does not exert any noxious action on lead when the metal is in its ordinarily dull state.' The experience of Inverness and Whitehaven, both supplied with lake-water of equal purity, and of powerful action on bright lead, is said to bear out this result. A coating is held to be formed on the surface of the metal, which protects it from further chemical action. Still there are opposing facts to shew that this protective action is not always to be relied on; and that water that has passed through any considerable length of lead pipe, or stood for some time in a short one, or in a cistern, should never be used without care; a ninth part of a grain of lead per gallon has been known to derange the health of a whole community.

A remarkably soft water, obtained from Bagshot Heath, near Windsor, was found to have poisoned some of the Queen's hounds, and brought on painters' colic on one of the huntsmen. On this water Dr Clark has made the following statement to the General Board of Health: 'Through the kindness of Sir James Clark, I obtained a specimen of this water, and in a few days came to the unexpected result that filtration would separate the lead. Thus, a very simple practical means for separating lead, wherever it contaminates water, was discovered. This was in the summer of 1843; but the process first came into practical use in spring 1844. At a marine villa of Lord Aberdeen's, some of the servants suffered in health from lead in water derived from pipes. Sand-filters were put up under my direction at this villa, and subsequently at Haddo House. On making inquiry recently at his lordship's agent in Aberdeen, I learn that the filters have been in use ever since, and that the waters have been tested from time to time, without any lead having been discovered in them.' The experiment has been recently tried on a large scale at Sydney, and with success.

Organic Impurities.

The contamination of water by vegetable and animal substances in a state of putrid decomposition, and by the minute forms of life bred among such impurities, takes place in various ways. The most obvious and abundant source of this class of ingredients is the sewage and refuse of towns, and next in order may be ranked the contact with soils rich in organic matter. Among organic impurities may be classed offensive gases, such as carburetted, sulphuretted, and phosphuretted hydrogen; vegetable fibres in a state of rottenness; putrefying products of the vegetable or animal kingdoms; starch, muscular fibre, &c.; urea and ammoniacal products; vegetable forms—algæ, confervæ, fungi, &c.; animalcules—infusoria, entomostraceæ, annelidæ or worms, &c.

Water falling on a growing soil, and running off the surface to lie in stagnant ponds, is in very favourable circumstances for being tainted with vegetable and animal life. Water-plants will spring up and feed numerous tribes of animalcules, and each pool will be a constant scene of vitality. In such a state the water is usually unfit for drinking; the palate instantly discerns a disagreeable taint, and no one will use it who can do better.

The surface-water of a district overgrown with peat-

* The water of Loch Katrine is remarkably well aërated, having 7¼ cubic inches of air per gallon, of which 2¼ inches are oxygen. Dr Clark has a suspicion that the oxygen may turn out to be in some different state or modification from common oxygen.

moss has usually a peaty flavour, as well as a dark and dirty colour. The infusion of peat does not breed animalcules, being a strong antiseptic; but it is an objectionable ingredient nevertheless. Very slow filtration has been found to remove the colour of the infusion; but if the filtered water be exposed to boiling or evaporation, the colour returns, shewing that the peaty matter has not been altogether got rid of. Lime removes the peat most effectually, but there is both expense and risk in applying it. It is perhaps doubtful whether any specific unwholesomeness can be justly attributed to peat-water; but it is unpalatable, and the use of it is shunned by the inhabitants of peaty districts, especially in the hot months of the year, and even by cattle. The presence of peat in the lands used as collecting-grounds for surface-water—and it is generally such worthless tracts that are so employed—is a disadvantage attending that mode of supply.

Chalk-water, which, as it issues from a spring, is perfectly free from organic matter, has a source of contamination within itself. When exposed to light and air, the duplicate dose of carbonic acid that keeps the chalk dissolved, becomes decomposed; and the carbon of the decomposed acid gives rise to a green vegetation which soon acquires an offensive marshy smell. This subject will be further noticed when we come to speak of Clark's process for purifying chalk-water.

Organic matter in a putrefying state forms the worst kind of contamination that water can have. Though we may not know the precise effects of these impurities on the animal system, the single fact of their rendering the water repulsive to the taste, and nauseous to the stomach, would be sufficient to condemn their use. What is disagreeable to the senses, must be presumed to be unwholesome in addition, until the contrary is proved. Though no one has ever yet gone the length of maintaining, as a general truth, the wholesomeness of water abounding in vegetation, insects, and decaying matter, yet the water of the Thames, even within the influence of the tides, where it is contaminated by the whole sewage of the metropolis, found defenders until lately, on the plea that the amount of impurity was too small to do harm. This ground is at length given up; but Thames water above Teddington Lock is still sanctioned as safe water for the companies to supply to the inhabitants of London, notwithstanding the sewage of the numerous populous towns that the river receives above that point. As to this plea of smallness of amount, the highest medical authorities hold that it is impossible to say how small a quantity of organic matter in a state of fermentation may not do harm. The powerful effects of vaccination are produced by an almost imponderable quantity of organic vaccine matter. A very minute portion of organic matter present in water containing sulphates, is sufficient to decompose these sulphates, and render the water offensive, from the discharge of sulphuretted hydrogen gas.

We are not, however, left merely to presume that organic impurity in water is prejudicial to health. At a meeting of the Society of Arts, London, 1856, when the whole subject of water-supply was discussed, the chairman adduced the following striking facts: 'He would quote to them the results of a gigantic experiment which had been undesignedly conducted on half a million of human beings, and which would set this fact in a strong light. It happened that, in the last epidemic of cholera, a certain half million of population, dwelling contiguously over one large area, were drinking different waters; some from private wells, but the larger number—about four-fifths of the whole—from two commercial supplies. There were the mains of two rival water-companies going through the district, often literally side by side; one company supplying nearly 25,000 houses, the other nearly 40,000; so that in this vast experiment there were immense masses of population living, as far as could be judged, in all respects alike, except as to the one difference of their water-supply only. And that difference was, that one company drew its water from high up the Thames, where it was of comparative excellence, while the other drew its water from low down the river, where it was profusely contaminated with town-drainage. Among the population to which he alluded, there were in 1853-4 more than 4000 deaths from cholera; and when the epidemic had subsided, an inquiry was made, house by house, as to those deaths, and as to the water-supply of the several houses where they had occurred. The inquiry was conducted with every precaution, to avoid sources of fallacy; and the result was this: In the one set of houses, the mortality per 10,000 of the population was 37; in the other set of houses it was 130—that is to say, the cholera death-rate was 3½ times as great in the one set as in the other. It also fortunately happened in this very decisive case, that further information could be procured, so as to present almost a duplicate experiment. The returns of the Registrar-general had made it possible to ascertain the mortality during the preceding epidemic of cholera—that of 1848-9. Going back to that period, it was found that the mortality from cholera was about equal in the two groups of houses. The mortality per 10,000 of population was in the one case 125, and in the other 118. The tenantry which in the epidemic of 1853-4 suffered a cholera death-rate of only 37, had in 1848-9 suffered a death-rate of 125; and why? At that time, instead of drawing a comparatively pure supply from high up the river, it was drawing from nearly the same source as that other company which, on the late occasion, contrasted so unfavourably with it. Now, these unintended experiments had been on so large a scale that they might be considered conclusive; and as the difference between the two waters in question was only that one of them contained a large admixture of town-drainage, they might be considered to establish the extremely dangerous tendency of this contamination during periods of epidemic cholera. Among the population supplied with foul water, the death-rate was three or three-and-a-half times greater than among those who had the advantage of a more wholesome supply.'

Living Products of Organic Impurity.

We have already made repeated allusions to the occurrence of living vegetation and animals in water, of which some forms are visible to the naked eye, while innumerable others are disclosed by the microscope. These products in the London waters have been carefully studied by Dr Arthur Hassall, who has given valuable information respecting them, bearing on the practical arrangements for maintaining the purity of a town supply.

Dr Hassall states that the deeper wells, and spring-water in general, contain little or no living organic matter. Consequently, it is quite possible to obtain a liquid perfectly free from animalcules and vegetation; and *it is not true that every drop of water teems with life.* The presence of living creatures, vegetable or animal, discernible either by the naked eye or by the microscope, is a proof of organic taint in the water, and is one of the tests of this kind of impurity.

With respect to rain-water, Dr Hassall states, in his evidence before the General Board of Health: 'I have made several examinations of rain-water immediately after its descent to the earth, obtained in both town and country, and can confidently assert that it does not, in general, contain any form of living vegetable or animal matter.'

The conditions necessary for the development of vegetation and animalcules, over and above the presence of matter for them to feed on, are *air*, *light*, and *stillness*.

With regard to the probable effects on health of living creatures contained in water, Dr Hassall's observations are worthy of attention: 'All living matter contained

in water used for drink, since it is in no way necessary to it, and is not present in the purest waters, is to be regarded as so much contamination and impurity—is therefore more or less injurious, and is consequently to be avoided. There is yet another view to be taken of the presence of these creatures in water—namely, that where not injurious themselves, they are yet to be regarded as tests of the impurity of the water in which they are found.'

The grosser kinds of organic matter held in suspension in water are visible to the naked eye; the minuter are revealed by the microscope. A ready way of ascertaining the presence of such impurities, is to fill a stoppered bottle nearly full of the water, and put it aside in some dark place where it will experience a temperature of about 70° of Fahrenheit. After allowing it to stand a few weeks, draw the stopper, and apply the nose to the mouth of the bottle; if the water smells in any perceptible degree, it may be pronounced a tainted water.

Means of Purifying Water.

The mechanical impurities of water, or the solid particles rendering it muddy or milky, may in most cases be removed by mechanical means. The two processes for this purpose are *subsidence* and *filtration*.

The effects of subsidence are strikingly seen in the case of rivers that pass through lakes. The Rhône enters the Lake of Geneva almost constantly, in summer at least, of the colour and consistence of pease-soup; it issues from the other end clear as glass and blue as the sky.

The subsidence of solid particles depends on their own weight, as compared with the weight of an equal bulk of water. To favour the process, the most perfect stillness should be allowed. It is expedient to have partitions placed in the subsiding reservoirs at short intervals, more effectually to prevent the agitation of the water. The water should be run off from the top, and not from the bottom. By making the bottom of the subsiding reservoir form a declivity from opposite sides, and providing means to let off the water occasionally from its lowest depth, it is possible to get quit of the subsided mud. It is always found of advantage in clearing water from solid particles, whether by subsidence or by filtration, to mix together streams of different qualities.

There are two methods of filtration in common use. One consists in forming a tunnel, either in a natural bed of sand or gravel by the side or in the centre of a river, and so situated as to become charged with water, which is then pumped up for use. This Natural Filter, first applied at Glasgow, and afterwards adopted at other places, is now believed to be a failure. The tunnel is often found to yield springs of an objectionable quality. A still more fatal objection, and one belonging to the very nature of the construction, is the changing level of the water in the river. It will happen that in hot weather, when water is most in demand, the level of the river is lowest, and the quantity passing through the filter least. The consequence is, that where this filter is employed, it becomes necessary in the summer months to take water from the river direct for the supply of the town.

The other method is to construct artificial filters. This is done by forming a basin, having the floor nearly level, but slightly inclining towards a centre line, and made water-tight by puddling the bottom and sides with clay. On the floor is laid a series of layers of gravel, coarse at first, and getting gradually finer upwards; next a layer of slate-chips or sea-shells, then one of coarse sand, on which is placed the actual filtering layer of fine sand. The depth of this layer is from twelve to thirty inches, that of the entire mass from four to six feet. The water being admitted gently on the top of the sand, sinks down and is conducted by a series of channels, generally of tile-pipes, into the main drain. A filter in a clean state will pass from twelve to eighteen vertical feet of water in twenty-four hours. The solid matter intercepted does not penetrate more than three-fourths of an inch into the sand, so that by removing a very thin film from the surface, the filter is again clean. What is scraped off the top, is capable of being washed and put again to use. 'This process of filtration,' says Professor Clark, 'is efficacious in removing mechanical impurities to an extent that could scarcely be believed without seeing the process.'

The cleansing power of sand can hardly be accounted for on the theory of mere mechanical interception. Though there is no chemical action, strictly speaking, there is no doubt that the attraction of adhesion is at work—a power that plays a greater part in natural processes than has generally been assigned to it.

Some substances manifest this adhesive attraction more strongly than sand, and have therefore still greater efficacy as filters; though practically, and on the large scale, sand is the most eligible. Powdered charcoal has long been known as a powerful filtering medium, attracting and detaining especially organic matter. Animal charcoal, or that derived from burning bones, is still more efficacious than wood charcoal. A filter of animal charcoal will render London porter almost colourless.

According to recent researches, it would seem that loam and clay have similar properties, and may be made available as filters. Professor Way states that 'they have powers of chemical action for the removal of organic and inorganic matters from water, to an extent never before suspected.' The filthiest liquids, such as putrid urine and sewer-water, when passed through clay, dropped from the filter colourless and inoffensive. The clay used was that known as pipe-clay.

Filters for domestic use will be noticed in the number on HOUSEHOLD HINTS.

Softening of Hard Water—Clark's Process.—This is one of the most beautiful applications of science to the arts of life that could perhaps be named. We extract the inventor's own account of it, as given in a paper read before the meeting of the Society of Arts, already alluded to:

'In order to explain how the invention operates, it will be necessary to glance at the chemical composition and some of the chemical properties of chalk; for while chalk makes up the great bulk of the matter to be separated, chalk also contains the ingredient that brings about the separation. The invention is a chemical one for expelling chalk by chalk. Chalk, then, consists, for every 1 pound of 16 ounces, of—lime, 9 ounces; carbonic acid, 7 ounces.

'The 9 ounces of lime may be obtained apart, by burning the chalk, as in a lime-kiln. The 9 ounces of burnt lime may be dissolved in any quantity of water, not less than 40 gallons. The solution would be called lime-water. During the burning of the chalk to convert it into lime, the 7 ounces of carbonic acid are driven off. This acid when uncombined, is naturally volatile and mild; it is the same substance that forms what has been called soda-water, when dissolved in water under pressure.

'Now, so very sparingly soluble in water is chalk by itself, that probably upwards of 5000 gallons would be necessary to dissolve 1 pound of 16 ounces; but by combining 1 pound of chalk in water with 7 ounces additional of carbonic acid—that is to say, as much more carbonic acid as the chalk itself contains—the chalk becomes readily soluble in water, and when so dissolved, is called bicarbonate of lime. If the quantity of water containing the 1 pound of chalk with 7 ounces additional of carbonic acid, were 400 gallons, the solution would be a water of the same hardness as well-water from the chalk-strata, and not sensibly different in other respects.

'Thus it appears that 1 pound of chalk, scarcely soluble at all in water, may be rendered soluble in it by either of two distinct chemical changes—soluble by

being deprived entirely of its carbonic acid, when it was capable of changing water into lime-water, and soluble by combining with a second dose of carbonic acid, making up bicarbonate of lime.

'Now, if a solution of the 9 ounces of burnt lime, forming lime-water, and another solution of the 1 pound of chalk and the 7 ounces of carbonic acid, forming bicarbonate of lime, be mixed together, they will so act upon each other as to restore the 2 pounds of chalk, which will, after the mixture, subside, leaving a bright water above. This water will be free from bicarbonate of lime, free from burnt lime, and free from chalk, except a very little, which we keep out of account at present for the sake of simplicity in this explanation. The following table will shew what occurs when this mutual action takes place:

Agents.		Products.	
Bicarbonate of lime in 400 gallons ...	Chalk............ 16 oz. with	= 16 oz. of chalk	= 2 lbs.
	Carbonic acid 7 oz.	= 16 oz. of chalk	
Burnt lime in 40 gallons of lime-water..................................	9 oz.		

A small residuum of the chalk always remains not separated by the process. Of 17½ grains, for instance, contained in a gallon of water, only 16 grains would be deposited, and 1½ grains would remain. In other words, water with 17½° of hardness, arising from chalk, can be reduced to 1½°, but not lower.

'These explanations will make it easy to comprehend the successive parts of the softening process.

'Supposing it was a moderate quantity of well-water from the chalk-strata around the metropolis that we had to soften, say 400 gallons. This quantity, as has already been explained, would contain 1 pound of chalk, and would fill a vessel 4 feet square by 4 feet deep.

'We would take 9 ounces of burnt lime, made from soft upper chalk; we first slack it into a hydrate, by adding a little water. When this is done, we would put the slacked lime into the vessel where we intend to soften; then gradually add some of the water in order to form lime-water. For this purpose, at least 40 gallons are necessary, but we may add water gradually till we have added thrice as much as this; afterwards, we may add the water more freely, taking care to mix intimately the water and the lime-water, or lime. Or we might previously form saturated lime-water, which is very easy to form, and then make use of this lime-water instead of lime, putting in the lime-water first, and adding the water to be softened. The proportion in this case would be one bulk of lime-water to ten bulks of the hard water.'

It is of importance that the lime or lime-water—that is, the softening ingredient—be put into the vessel first, and the hard water gradually added, because there is thus an excess of lime present up to the very close of the process, and this circumstance is found to render the precipitation of the carbonate of lime produced in the process more easy. The conductor of the process knows when he has added enough of the hard water to take up the last excess of the lime, by applying what is called the silver test. The carbonate of lime when first formed gives to the mixed waters the appearance of a well-mixed whitewash; but in a few hours it subsides and leaves the water above perfectly clear. The softened water thus obtained is stated to have no action on lead pipes or cisterns, as many soft waters have. One ton of burnt lime, used for softening, will produce three and a half tons of precipitate, which forms a very superior kind of whiting, though it has not as yet been turned to any commercial account. The present water-supply of the metropolis, if subjected to Clark's process, would deposit about fifty tons of chalk daily.

The process has been in operation on a large scale for upwards of two years at the Plumstead water-works, near Woolwich, where 600,000 gallons daily are operated upon with the most satisfactory result. The water there, as pumped up from the chalk-strata, has 21¼° of hardness; after the process it has 8¼°. Of this remaining hardness, however, only 1¼° are due to chalk; the other 7° arise from sulphate of lime, on which neither liming nor boiling has any effect. It may be removed by carbonate of soda, which precipitates it as carbonate.

Clark's process is not confined in its effects to softening; it has a decided influence as regards organic impurities. It has been already seen that chalk-water has within itself an active source of corruption. The carbonic acid which it is so ready to part with, favours the growth of plants, and these are followed by animals which soon die, and lead to much impurity. The precipitation of the chalk, for one thing, takes away the source of these impurities, as was strikingly proved by an experiment made by the Plumstead Water-company. They omitted the liming process for a time, and supplied the water to the consumers unsoftened. In a few days, the surface of the water in the reservoirs became covered with masses of vegetation, and gave out a stench of decaying vegetable matter; though nothing of the kind had been seen or felt before. 'Not slow were the consumers in discovering the sudden hardness that had come over the water, nor were they silent under the discovery; and the company gave up their instructive experiment at the end of three weeks.'

As regards organic contamination already existing in water, the precipitated chalk carries a large proportion of such matter along with it. When Thames water was submitted to the process, it was found that the quantity of organic matter had been reduced to one-third of what it was before the lime was added. Nor is it merely the suspended matter that is carried down; the dissolved matter is also reduced. Still, it is not pretended that all the dissolved organic matter is thus removed. Water much contaminated still retains, even after liming and filtering, offensive qualities, and sewage ingredients liable to putrefactive changes. This renders it much to be regretted that the Thames and other contaminated open channels should still be the sources from which the water-companies are allowed to draw the supplies of the metropolis; for though the application of the liming process would undoubtedly improve them, more perhaps than any method of filtering, they can never be rendered desirable, or even safe. 'Even in the water supplied by the Lambeth Company, which is comparatively the purest of the whole, organic productions, dead and living, animal and vegetable, are found in not inconsiderable numbers; and this water furnishes the type of that with which, in 1855, the greater part of London and its vicinity will be supplied, in accordance with the recent Act by which the water-supply of the metropolis was regulated. The metropolis, then, after that year, will still continue to be supplied with river-waters containing various kinds of organic matters, including numerous living productions. Now, that there is no necessity that this should be, has been clearly proved by the case of the Plumstead Water-company, which supplies a water entirely free from living organic productions of every description.'* It is demonstrable that the chalk-strata around London would furnish an inexhaustible supply of spring-water, which, after liming, would be superior even to that of Plumstead.

Natural Process of Purification from Organic Matter.—We have seen that though by means of sand and other filters, or of the liming process, organic contamination of water may be much reduced, there still remains enough to render the water unsafe for use. Is water then, once corrupted with organic matter, hopelessly and permanently so? This question can be answered in the negative. Filthy water has a tendency to purify itself; and this in two ways. In the first place, in any shallow stream of polluted water, such as

* *Appendix to Report of the Committee for Scientific Inquiries in Relation to the Cholera Epidemic of* 1854, p. 271.

the kennels of a street, there may be observed long brushes of a sort of slimy vegetation adhering to every projection of the bottom. All this matter has been disengaged from the water, which thus flows away so much the purer. The second and most effective part of the natural purification consists in the actual decomposition of the impurities. The nitrogen of the decaying matter, then, goes to form nitric acid, which, uniting with bases, forms salts of the class called *nitrates*, of which saltpetre is one. Thus, what was in a state of putrefactive change, offensive to the senses, breeding loathsome insects, and causing dangerous disorders, is changed in course of time into a stable and harmless product. This process is constantly going on in rivers and other waters containing organic matter. Dr Angus Smith found that the amount of dissolved nitrates contained in Thames water at different points from its source to London Bridge, went on increasing as the river became mixed with sewage from the towns on its banks. Nature was thus seen working to counteract the evil. In the Thames, especially near London, the contamination goes on at a rate far beyond the power of natural purification; but it is clear that nature is constantly abating it, and that, but for this process, it would be much greater than it actually is. We can thus easily conceive how a river, very much contaminated with organic impurities at one part of its course, may, after flowing a long way through an uninhabited tract, be quite restored to its natural state.

This process is much favoured and hastened when the water is made to percolate or filter very slowly through beds of earth. Dr Smith found an extraordinary amount of nitrates in some of the London wells. If the filtration has been sufficiently prolonged to convert all the decaying matter into nitrates, the water will be pure, as far as the organic taint and the presence of animalcules are concerned, and will, in fact, be neither disagreeable nor unwholesome, the amount of the dissolved nitrates being unimportant. A knowledge of this purifying process is of consequence in allaying apprehensions as to the impurity of wells and springs suspected of too close proximity to drainage or other cause of pollution. If a tolerably thick bed intervene, the chances are, that a complete purification will be effected during the percolation.

There can be little doubt that part of the purifying effect of artificial filtering takes place in the way now described. Not merely can the grosser particles not get through the narrow interstices of the filter, but impalpable matters are retained by a sort of vegetative adhesion. Dr Smith, again, has proved by direct experiment that decomposing organic matter passed through a filtering-bed is changed into nitric acid. 'A jar, open at both ends, such as is used with an air-pump, was filled with sand, and some putrid yeast, which contained no nitric acid, was mixed with pure water, and poured on the sand, and allowed to filter through. The production of nitric acid was abundant.' It is not improbable that other earthy matters, such as loam and clay, may have a still more decided influence in hastening the formation of the nitrates; and perhaps by imitating more closely the slow mode of filtration by which nature converts surface-water into spring-water, it may yet be practicable to make the most contaminated waters fit for use.

Storage and Distribution.

The engineering principles connected with water-works are touched on in the number on CIVIL ENGINEERING. We have here to consider modes of storing and distributing, as they affect the quality of the water and the comfort and health of the population.

The extent of the storage in reservoirs depends on the nature of the supply. If water is derived from perennial springs, whose minimum flow equals the maximum demand, the storage may be the least possible. If a river is the source, the reservoirs should be large enough to hold such a stock as will carry the consumers over the periods when the river is polluted by rains; they should also be large, on the principle of allowing time for purification by subsidence, especially if artificial filtration be not employed. In places where the supply is obtained from surface-drainage, the practice has been to build reservoirs capable of containing a five or six months' supply, it being necessary to provide against the greatest droughts that ever happen in any season.

The reservoirs should be deep, so as to prevent vegetation; and the distributing or service reservoirs should be roofed.

In distributing water over a town, two different methods have been adopted, known respectively as the *intermittent* and the *constant* systems of supply. On the intermittent system, water is laid on once a day, or once in two days or three days, as the case may be, and fills a tank attached to every separate house, and from this tank the water is drawn off as required. The feeding-pipe of such a tank or cistern is provided with a ball-cock (see fig.), which ingeniously shuts off or admits the supply, as the cistern may be full or empty. On the constant system, no tank is absolutely needed, but the house-pipes are kept constantly charged through their unbroken connection with the distributing reservoir, which must therefore be higher than the highest house to be served. The intermittent supply was until lately employed everywhere in the metropolis; but it is almost universally admitted that the other system is vastly superior in every respect; and, in consequence, all new works are erected on this system. The disadvantages of the intermittent practice have been strongly set forth in all the recent official reports on sanitary improvement: the expense of the erection and repair of cisterns, the trouble requisite to keep them clean, the contamination of the water by the neighbourhood of sources of pollution, the frequent waste of water that occurs, the difficulties imposed on the poorer class of tenements where cisterns are not provided—are a few of the objections urged against this mode of supply. Dr Hassall's examination of the cistern-water of London revealed a frightful amount of pollution—the consequence of placing water already impure in circumstances where the impurity is still further aggravated.

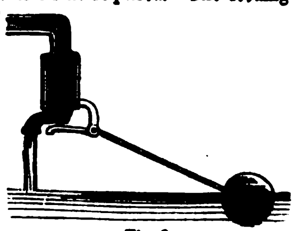

Fig. 2.

One important advantage, arising from the constant system, is the ease with which water can be had in time of fires. The water being supplied at high-pressure, all that is necessary is to affix a hose to the water-plug in the street, when a jet corresponding in height to the pressure is obtained, which can be immediately directed against the fire.

The ratio of the supply to the population varies in different towns. In Edinburgh it is 25 to 30 gallons for each individual; in Glasgow it is 36 to 38 gallons. This includes the water furnished to works of various kinds. The London supply has nearly doubled within the last six years, being now 81,000,000 gallons, distributed among 328,561 houses, which gives 246 gallons per house. The works of the ten companies have cost upwards of £7,000,000. There are 2086 miles of main and branch pipes (exclusive of private service pipes); the subsiding reservoirs cover 141 acres, and the filter-beds 40 acres.

Cisterns, Pipes.—Owing to the action of water on lead already described, it is desirable to avoid the use of that metal in connection with water. With regard to lead *pipes*, if the precaution is taken when the water has stood for any time in them, of allowing the first portions to run off before any is taken for use, little

danger can arise; but either lead *cisterns* should be wholly avoided, or means taken to ascertain whether they contaminate the water; and if so, a remedy should be applied. There are various substitutes for lead as a lining for cisterns. Slate slabs are highly recommended. Gutta-percha is also found to be an easily fitted, cheap, and durable lining. For a few days, the water tastes of the naphtha used in applying the lining; but afterwards no kind of water, not even acids, have any action on the gutta-percha. Pipes of gutta-percha may also be used; they are cheap, and easily fitted up.

Common Wells.—The simplest of all water-supplies is that of a cottage or farmhouse in the country, with a good spring rising to the surface close by. And yet what a poor use is usually made of such a precious boon! The country well is generally a simple cavity to receive the spring, rudely lined, it may be, with stones, but with open mouth, into which dust and dead leaves are blown by every wind, and foul surface-water is trickling from all sides. Being exposed to the light, there is generally a profuse vegetation on the bottom and sides, and, in addition to these impurities, it is further muddied by the dipping in of buckets, often dirty on the outside. Who has not been disgusted, when asking a drink at a cottage, to get water thick with dust and visible impurities, knowing, at the same time, that it might be so easily remedied? A surface-spring should always be covered, and made to issue by a pipe; half a day's labour to create a fall, and a clay drain-tube, will generally convert a filthy puddle into a crystal fount. It is singular to see this blindness to the impurity of water in people otherwise cleanly enough. This is a subject worth the attention of country physicians and clergymen. The evil effects of drinking impure water are not confined to towns. May not the putrid sore throat and malignant fevers that often sweep away whole households in the country, especially in autumn, be partly owing to the cause now pointed at?

Deep wells should invariably be covered, and carefully protected from the infiltration of superficial ooze. The situation of pump-wells is often singularly ill chosen in this respect.

Artesian Wells—so called from Artois, a province in the north of France, where, it appears, the greatest attention has been paid to the discovery of subterranean springs—are distinguished from common wells by the circumstance of their waters rising above the surface, often to a considerable height, and with considerable violence. This fact, that water will rise spontaneously to and above the surface, in certain localities, when bores of various depths are made into the earth, seems to have been long known to mankind. An Alexandrian writer of the sixth century narrates, that 'when wells are sunk in the oasis of the desert, to a depth varying from 100 to 500 ells, water springs from the orifices, so as to form rivers, of which the farmers avail themselves to irrigate their fields.' In more modern times, travellers relate that, in some parts of the Desert of Sahara, the natives sometimes bore the earth to the depth of 200 fathoms, and always succeed in finding water, which flows often up the bores with such force, as to drown those engaged in making the excavations. In China, also, and in European countries, there are proofs of wells of this nature having been early formed.

Artesian wells are common on the continent, particularly in France, which consequently furnishes the finest examples. That of Grenelle, near Paris, is, we believe, the most gigantic, the borings being carried through tertiary and chalk strata to a depth of 1798 feet, or one-third of an English mile. The bore is 20 inches in diameter at the orifice, but is contracted by stages, till at the bottom it is only 7 inches. The bore is lined with iron tubing; and the current, which discharges between 500 and 600 gallons per minute, rises to a height of 30 or 40 feet above the surface. The work was commenced under the superintendence of M. Mulot in November 1833, and finished in February 1844 at an expense of 303,000 francs. In Britain, as well as in France, there are others of large dimensions. In many wells formed on the Artesian principle of penetrating through an impervious stratum to the water-bearing stratum below, the water rises only partially up the shaft or boring, and not quite to the surface. This is the case with the wells of London that are sunk through the stratum of clay. The level in these wells is annually sinking, shewing that this source of supply is already drawn upon to the full.

The geological and hydrostatic principles upon which the forcible discharge of Artesian fountains depends, are sufficiently obvious. The best occur in secondary and tertiary basins, the principle being as follows: Let the annexed section represent a tertiary basin, composed of

Fig. 3.

alternating strata of sand, clay, gravel, and loose sandstone. It is clear that the thick bed of sand and gravel, *a*, lying between two layers of impervious clay, *b* and *c*, can have no outlet for the water with which it is saturated by percolation. It is, in fact, a great subterraneous sheet or reservoir of water, whose maximum pressure is at the bottom of the basin. Below the London clay there is an immense reservoir of this kind. Let a well or bore be sunk in the valley, and the result will be, so soon as the bore strikes the bed of gravel, a rush or jet of water, forcible in proportion to the extent of the bed, and the height to which its sides rise above the surface of the valley. Depending upon these principles, no Artesian well should be attempted without consulting the geologist or mining-engineer. A deflection of the strata, the occurrence of a dike, or some such phenomena, which the geologist alone can interpret, may render abortive years of labour.

Artesian wells are generally formed by *boring*, which is performed in much the same way as a quarryman bores for blasting. The boring-head, or ram, consisting of a mass of iron, with steel chisels fixed in its under side, is made to rise and fall by a rod, or—according to the Chinese method, which is found preferable—by a rope, to which a certain torsion is given. Sometimes the débris is lifted by the ram itself; in other cases a separate auger, or shell pump, is from time to time applied. It is necessary, in soft strata, to line the bore with iron tubing.

Fountains—Jets-d'Eau.

Fountains or jets-d'eau are contrivances by which water is violently spouted or projected upwards in a continuous stream, so as to become at once ornamental, refreshing, and salubrious to the locality in which they are situated. The projecting force is acquired either from the hydraulic pressure of the water at the fountain-head, by the spring and elasticity of a confined volume of air, or by mechanical appliance; but generally by the first. (See HYDRAULICS and PNEUMATICS.) The water is conveyed from the reservoir to the fountain in pipes, and if the orifice from which it issues be directed upwards, it will spout to a height approaching that of the reservoir.

Decorated fountains of this kind were much in request among the Greeks and Romans, not only in their streets and gardens, but also in the courts of their houses; and this fondness for fountains still exists in Italy and the East, where there are numerous elaborate and fanciful designs. The French are also celebrated for their fountains, those at the Tuileries, Versailles, and

St Cloud being superb structures; and indeed, with the exception of our own, most of the large towns of Europe are adorned and refreshed by these contrivances. The most remarkable jet-d'eau in the world is said to be that at Cassel in Germany, where the waters rise from an orifice of twelve inches diameter to a perpendicular height of 200 feet. The source from which it is supplied is at the top of a mountain near by, being about 500 feet above the level of the town. The fountains of the Sydenham Palace are on a grand scale. The jets-d'eau, and cascades of the numerous basins, contain six times the amount of water thrown up by the Grands Eaux at Versailles.

Viewing jets as auxiliaries to health, as well as ornaments, we are inclined to advocate their erection wherever it is practicable. In our public gardens and squares, along promenades, and at the crossing of streets, nothing could be more appropriate and ornamental, independent of the cooling effect which they must exert over the surrounding atmosphere in summer. Where the supply of water is abundant, there is every scope for the ingenuity of the artist and engineer in the designing of fountains—from the most grotesque and fanciful, to the most severely classical conception. Nor is there any reason why small, permanent, or portable fountains should not be more generally introduced into our market-places, shops, and public buildings, where the atmosphere is apt to become heated and contaminated, producing oppression, listlessness, and languor.

BATHS—WASH-HOUSES.

Referring the reader to our article on the Preservation of Health for the sanitary value of personal ablution, we shall here treat of baths as a social arrangement, and of the various mechanical appliances requisite for the establishment of a system.

BATHS OF THE ANCIENTS.

The use of the bath, natural or artificial, has existed, in all probability, from the beginning of the world, since it is founded in the most natural wants of man. The Greeks knew the use of warm baths in the time of Homer. At a later period, they had public baths attached to the *gymnasia*, and the richer families also had baths in their private houses.

The Romans were late in introducing artificial baths. But in the reign of Augustus, they began to give to their warm baths that air of grandeur and magnificence yet to be observed in the ruins which remain. Bathing among the Romans was not a mere dip. It embraced a variety of operations, including gymnastic exercises, performed in a succession of apartments, and with water of all temperatures, accompanied also with the use of unguents and perfumes. At first, the public baths were only opened at two o'clock in the afternoon, and closed at five, the sick alone having a right to enter them at any time; but the hours for bathing were greatly increased in number by the later emperors. The baths were frequented indiscriminately by individuals of all ranks; the noblest and richest persons there finding themselves mingled with the poorest plebeians. Besides baths, the same structure contained theatres, temples, festive halls, promenades planted with trees, academies, libraries, &c.

It was not only the Roman metropolis which contained public and private baths; they existed in all the towns of Italy, and in the palaces of nobles and freedmen; they were found also in all the Roman provinces. The greater number of these magnificent edifices, which, during the most illustrious period of the empire, had constituted the pride and delight of Rome, were destroyed by the vandalism of the barbarian hordes. Those which were not pulled down, were otherwise employed, or, being no longer repaired, gradually fell into ruin. In the middle ages, baths on a more moderate scale were introduced as the ancient structures disappeared. 'The idea,' says Grosley, 'was due to the Arabs, among whom the arts and sciences had found an asylum. The Crusades and commerce had opened up to Europeans the countries which flourished under the rule of this people, and the natural taste for imitation did the rest. The vapour and public baths were, for a long period, as much frequented in Europe as they are at the present day in the Levant.'

MODERN BATHS AND WASH-HOUSES.

Although the increasing use of linen has much diminished the hygienic necessity of the bath, and has occasioned the ruin and neglect of the establishments of the middle ages, yet public attention has not ceased to be directed to the advantages of such establishments—thanks to the salutary counsels of medicine, the progress of civilisation, and the amelioration of the material comforts of the masses. 'Eminent physicians,' says Dr Clark, lamenting our inferiority in this respect to continental nations, 'have endeavoured to draw the attention of the British government to the importance of public baths, and of countenancing their use by every aid of example and encouragement.' Since that physician wrote, the institution of baths has much engaged the public attention. The houses of our higher classes are now invariably fitted up with accommodation for hot and cold bathing; portable baths on the sponge, shower, or plunge principle, are common in the dwellings of the middle classes;* and deficient as we yet are, the last ten years has witnessed the erection of a number of private and public establishments, at which the masses may enjoy a bath for the merest trifle of their weekly earnings. Bathing should be deemed a necessity, not a luxury. The great majority of our artisans and factory-workers are engaged in labour of a kind by no means cleanly, and without daily ablution of some sort or other, disease, injured constitutions, and debased moral sentiments, are certain, sooner or later, to be engendered.

We shall speak presently in detail of public baths; but where steam-engines are employed in connection with cotton-factories or other works, there is usually a certain quantity of waste steam or waste hot water at disposal, which could, at an insignificant cost, be directed into baths for the use of the workmen of the establishment; and we hope this will be done wherever it is practicable. The improved health and cheerfulness of the parties benefited will be more than compensatory for the necessary outlay. We are aware of one instance where seven baths were comfortably fitted up at the small expense of £80, in which the men and women bathe on alternate days, to the number of from thirty to eighty a week—paying a mere trifle to the keeper, who attends an hour and a half each evening, and finds towels, soap, &c., nothing being charged by the proprietors for the original outlay.

Another modern improvement, the public wash-house, calls for mention. In a country where the labouring-classes are in a comparatively easy condition, and thinly scattered, the house is at once the domestic brewery, bakehouse, and laundry, as it is the family sanctuary. But where the masses are densely packed in lanes and alleys, where house-accommodation is dear and limited, where the necessaries of life have to be continually struggled for, and these conventional evils increased, in too many instances, by improvidence, the house is

* In absence of *permanent* baths—which ought to form part of every modern house of any pretensions, just as much as its kitchen or laundry—*portable* baths, now procurable at the iron-mongers in every variety, will be found to be no indifferent substitutes. For a permanent hot bath, the kitchen-range may be constructed so as to have a supply of from ten to twenty gallons of warm water always in readiness, and this, after the original outlay, at a cost almost inappreciable.

but a night-shelter, affording little or no convenience for the necessary operations of the housewife. Independent of this, in point of economy, a public wash-house is preferable to any number of isolated efforts. By co-operation, superior accommodation, better apparatus, and a cheaper and more satisfactory result, can be obtained; and thus the public wash-house, where self-paying and self-supported, may be classed among the co-operative arrangements which characterise the social features of the age. When we consider the amount of fuel required for a kitchen-fire on a washing-day, the time wasted by imperfect arrangements, the inconvenience experienced where the housewife has to wash, dry, and iron her clothes in the one sole room where she has to cook the family meals, and where that family has perhaps to eat, sleep, dress and undress, and perform all the minor offices of life, we can then appreciate the boon which a public wash-house is calculated to confer.

The general nature of a system becoming much more evident when illustrated by specific examples, we will give a brief account of the progress made in recent years in England towards the establishment of baths and wash-houses for the working-classes.

So far as concerns wash-houses, the credit of a reformer is due to Mrs Catherine Wilkinson of Liverpool, who, in a year of cholera, bravely offered the use of her small house, and the value of her personal superintendence, to her poorer neighbours, to facilitate the washing of their clothes at a time when cleanliness was more than usually important. The success attending the exertions of a single individual led to the formation of a benevolent society; and the success of this society led the corporation of Liverpool to the establishment of a small bath-house, containing eighteen private baths, and one vapour bath.

In the month of October 1844, a public meeting was held at the Mansion House, attended by many persons of wealth and influence, to encourage the formation of baths and wash-houses in London; hence resulted an 'Association for Promoting Cleanliness amongst the Poor.' Independently of this movement, a reform had already been commenced by a 'Committee for the Houseless Poor,' who, among other things, purchased or rented an old roomy building in Glasshouse Yard, surrounded by the poor and dense population of the London Docks district. A bath-house and a wash-house were fitted up; baths, cisterns, boilers, cold and hot water, towels, soap, soda, were provided; and the poor were invited to come in, and wash and bathe without expense to themselves. There were also provided pails, brushes, and whitewash, to those who would take the trouble to give a little cleanliness to their poor dwellings. For an expenditure of £900 within a given period, accommodation was afforded for 62,000 bathers, 73,000 washers and driers of clothes, and 15,000 ironers; besides the whitewashing of several hundred rooms and staircases. This was effected greatly through the benevolent exertions of Mr Bowie, a surgeon who applied himself with earnestness to the subject. This gentleman has recorded that women occasionally came many miles to wash their scanty supply of garments at that place: women, too, who had been compelled to *sell their hair* to purchase food for their children. The association, afterwards founded at the city meeting, sought two objects—to induce a wish for cleanliness among the poor; and to render public baths and wash-houses *self-paying*, as a guarantee for their permanency. Having obtained plans and estimates from architects, the association built a model establishment in Goulston Square, Whitechapel; but owing partly to a difficulty in collecting funds, the baths and wash-houses in that locality were not finished and opened until the year 1847; the cost, too, had been so enormously increased by the experiments incident to a new undertaking, that the entire outlay ultimately reached £26,000. In the meantime, another society had succeeded in establishing baths and wash-houses in George Street, Hampstead Road, favoured by a liberal arrangement on the part of the New River Company in the supply of water: this establishment was opened in August 1846. In the same year, parliament passed an act to enable borough-councils and parish vestries to establish public baths and wash-houses, supported by borough and parish rates, if the householders should sanction such a proceeding. In 1847, another act strengthened the former; and the two together contain the necessary clauses for defining the details of the plan. The chief of these clauses are—that the requisite funds may be raised on the security of the poor-rates, at 4 per cent., to be repaid by thirty yearly instalments; and that the minimum charges, for the benefit of the poor, should not exceed one penny for a cold bath, twopence for a warm bath, and one penny per hour for laundry conveniences. The parish of St Martin's-in-the-Fields was the first to take advantage of the new act; and before the close of 1852, six parishes had erected public baths and wash-houses, and in each establishment attempts were made to introduce improvements in the practical details. At the beginning of 1856, the list had nearly doubled. The original free but humble building in Glasshouse Yard had been abandoned; but the model establishment in Goulston Square, and the separate undertaking in Hampstead Road, remained; giving a total of thirteen public baths and wash-houses in the metropolis at the beginning of 1856.

It is not to be supposed that these efforts have been confined to London. Liverpool took precedence in date, and has since worthily maintained her interest in the matter. The baths and wash-houses first established are in Paul Street; the next, opened in 1851 in conformity with the provisions of the new act, in Cornwallis Street; and to these have since been added two others, at George Pier Head and Frederick Street. Hull, Bristol, Birmingham, Preston, Bath, Wolverhampton, Coventry, Plymouth, Chester, Sunderland, Bolton, Macclesfield, Oxford, Maidstone, Exeter, Rotherham, Colchester, South Shields, Dublin, Belfast, Glasgow, Dundee, and other towns, have since adopted a similar course; and it may safely be predicted that borough and parochial baths and wash-houses will increase in number year by year; for if they do not actually pay their full expenses at the low charges framed, the deficiency will be so small as to be practically unfelt by rate-payers.

When the legislature took up the subject, the purpose of the committee appointed in 1844 was in great part answered; but that committee continued to exist until 1855; and the energetic exertions of Mr Cotton, Mr Hawes, and Mr Woolcott, in their capacities as chairman, deputy-chairman, and secretary, were attended with very beneficial results, in drawing the attention of influential persons throughout the country to the advantages of public baths and wash-houses. One report from the committee contains the following highly interesting information concerning foreign countries: 'In consequence of the favourable report made to the French government by the commission appointed to inquire and report on the public baths and wash-houses in England, 600,000 francs were voted by the late National Assembly, to assist the promotion of such institutions in France, after the plan of the model establishment; and a scheme was set on foot for erecting fourteen establishments in Paris, for which 2,000,000 francs would be required. The municipality of Venice contemplate an expenditure there of £33,000 in the erection of baths on the same plan. The Norwegian government have applied to the committee for the plans, &c., of their wash-house at Goulston Square, as a guide for the erection of one at Christiania; and a subscription has been commenced for the erection of baths and wash-houses at Copenhagen. The Belgian government, and the authorities at Hamburg, Turin, Munich,

Amsterdam, Lisbon, and New York, have also been furnished with information on the subject.'

In nearly all the London establishments, which may also be taken as types of those in the country, the characteristic features are as follows: The baths for males and females are on opposite sides of the building, separated in some instances by the washing-room, and in others by the plunging-baths. The separate baths, in large well-lighted and well-ventilated rooms, are shut in by walls generally of slate; and the baths themselves, supplied with fifty or sixty gallons of water for each bather, are either of zinc or enamelled iron. There are two, three, or four classes of baths, charged differently according to the amount of accommodation afforded. At the St Martin's establishment, where there are only two classes of baths, it has been found that the second-class bathers are thrice as numerous as the first. Arrangements, slightly varying in different establishments, afford means for conveying hot and cold water to every bath. In some instances there are tepid as well as cold swimming or plunging baths; while two or three of them afford facilities for shower and vapour baths. Much more interesting, however, are the wash-houses, as examples of a great improvement. The washing-room is provided with numerous small compartments, doorless and roofless, each for one person. Each compartment contains a boiler and a washing-tub, with taps for hot water, cold water, waste water, and steam: all unlimited in quantity, wilful waste of course being guarded against. An American washing-board assists the operations; and a rack-work stand protects the feet. The steam from all the compartments is carried upwards to one great ventilating shaft. The 'wringing' of the wet washed linen is effected by putting the articles into a sort of perforated cylinder, which is then rotated with great velocity; the centrifugal force drives out the water through the perforations and interstices, leaving the linen, though damp, much drier than it can be made by the familiar laundry process. The clothes are then taken to the drying-room, where they are hung on frames or 'horses' in small chambers heated with hot air to about 200° or 210°. At first, great difficulties were experienced in conducting this process profitably, for a current of hot air carried off the value of a great deal of fuel; but a skilful method was at length adopted, and 10,000 or 12,000 articles of washed clothing can now be dried with £1 worth of fuel. In some of the improved establishments there is a drying compartment belonging to each washing compartment, effecting a manifest saving of time to the washers; in some of them, too, there is an ironing-board to each compartment, but the general plan is to have a large ironing-room, well provided with irons, ironing-blankets and boards, and heating arrangements. The charge is from 1d. to 2½d. per hour, according to the class and the accommodation. The amount of time and money saved, and discomfort avoided by the adoption of this excellent system, can only be appreciated by those who know the difficulties under which linen-washing is conducted in the cramped houses of working-people in densely populated towns.

With the presentation of a few figures, we shall conclude this part of our subject. It has been found by actual results, at the Goulston Square establishment, that 37,000 garments—an aggregate of all the usual kinds—belonging to 1370 washers, were washed, dried, and ironed in 3000 hours: that is, each woman, on an average, working about two and a quarter hours, began and finished the washing and ironing of her family stock of twenty-seven articles. Of course this last-mentioned number would be varied according to the station in life of the washer and her family; but taken as it stands, it affords some slight clue to the wardrobe-wealth of the Whitechapel district, so far as regards those who availed themselves of the public wash-houses—especially as it is found that, on an average, each washer washes for four persons. When the model establishment was first founded, the fuel for heating 1000 warm baths cost £3, 15s.; but by successive improvements, this cost was reduced to £1, 4s.* The valuable tables drawn up by Mr Woolcott shew the progressive advance in the baths and wash-houses of the metropolis, between 1848 and 1855—the number of establishments being increased from two to thirteen, and the receipts from about £2800 to £24,500.

The following table shews the ratio between the bathers, the washers, and the receipts, at the thirteen metropolitan establishments, in the year 1855:

	Bathers.	Washers.	Receipts.
			£
Whitechapel, ...	138,843	44,126	2690
St Martin's, ...	101,901	42,903	2210
St Margaret's, ...	70,517	59,516	1728
Marylebone, ...	139,926	23,790	2423
Greenwich, ...	55,210	5,201	897
St James, ...	97,581	40,483	1959
Poplar, ...	45,536	10,909	930
St Giles, ...	157,928	43,118	3501
Bermondsey, ...	79,986	21,267	1542
Lambeth, ...	121,912		2020
Davies Street, ...	63,307	16,074	1255
Belgrave Place, ...	70,101	12,119	1151
Hampstead Road, . . .	76,002	98,133	2191
	1,216,750	417,634	24,527

The whole number, bathers and washers, paid about 4d. each on an average. The following table refers to nine country establishments for the same year, 1855:

	Bathers.	Washers.	Receipts.
Liverpool:			£
Cornwallis Street, . .	114,527		1903
Paul Street, ...	53,491	12,381	906
George Pier, ...	54,460		1911
Frederick Street, ...		16,463	402
Hull, ...	50,113	8,513	573
Bristol, ...	37,907	18,056	629
Preston, ...	27,416	9,704	388
Birmingham, ...	91,214	6,081	1680
Maidstone, ...	32,818	8,875	361

Here also the average is about 4d.

The wash-house part of the scheme does not seem to succeed in Scotland. In Glasgow, the wash-houses have been given up; the baths, on the contrary, are flourishing; one of the two public establishments had, in 1856, 40,000 bathers, and is more than self-supporting. The case is much the same at Dundee and Aberdeen.

SEWERAGE AND DRAINAGE.

As efficient means should be taken to secure for our towns and cities a regular and abundant supply of pure water, so ought there to be a regular system of emission for that which is foul and waste. The rain which falls on our roofs and streets, and the waste water of our houses and public works, with all the animal and vegetable matter wherewith they are impregnated, must be regularly and speedily carried off, otherwise stagnation and putridity ensue, deleterious effluvia arise, and are inhaled by the inhabitants, and disease, suffering, and death are the inevitable consequences. The most obvious method of discharge is by open gutters; but as these are offensive and unsightly, the great object, both in ancient and modern times, has been to establish a system of underground sewerage.

Among ancient nations, the Romans carried underground sewerage to the greatest perfection; and it is worth while, in these days of sanitary preachments, briefly to glance at their *cloacæ*—a term which includes

* Might not still greater economy be effected *by transferring the heat from the used water to the clean*, on the principle explained in the number on WARMING?

not only the larger sewers which led to the Tiber, but the small drains or pipes of wood or clay leading into these. The whole city was thus intersected by subterranean passages. The most celebrated of these drains was the *Cloaca Maxima*, the construction of which is ascribed to Tarquinius Priscus, and which was formed to carry off the waters brought down from the adjacent hills into the Velabrum and valley of the Forum. The work is evidently of great antiquity. The arch of this cloaca is semicircular, and formed of three rings of voussoirs, as shewn in the annexed cut, being 14 feet in width, and 32 in height. The blocks are hewn, and joined together without cement. The erection of such spacious sewers to take off the drainage-matters of houses which were mere huts in comparison, contrasts painfully with the indifference shewn on these points by modern governments. In England, some years ago, the commissioners appointed to inquire into the Health of Towns reported that of fifty towns visited by them, forty-two were decidedly bad, and that scarcely one could be pronounced good as regards the state of the drainage. The importance to the health of the community of a good system of drainage, is too obvious to need much comment. Dr Southwood Smith, an eminent authority in all sanitary matters, says, he believes 'the immediate and direct cause of fever to be a poison generated by the decomposition of animal and vegetable matters.' He instances the case of Lambeth Square, where thirty-seven houses, previously visited by cholera and typhus, were, by the substitution of water-closets and drain-pipes for privies and cess-pools, freed from the recurring typhus, and escaped the following visitations of cholera that ravaged the surrounding streets.

Fig. 4.

The chief points connected with the construction of the main sewers of a town are noticed in the number on CIVIL ENGINEERING. We have here to speak of the drainage of the individual houses.

While the street-drains or main sewers are built of brick or other materials, the small drains for the separate houses may consist of earthenware tubes. The tube-system was at one time strongly advocated both for mains and branches; but experience has proved that the employment of earthenware tubes is not advisable where a channel of above twelve inches diameter is required. Within that limit, and therefore for house-drainage, pipes are allowed on all hands to be preferable in every way to brick-drains.

Mr Bazdgette, engineer to the Metropolitan Commissioners of Sewers, finds that a drain-tube of nine inches diameter will be sufficient to receive the drainage of from three to six small cottages or houses; and that each separate house should have a drain-tube of six inches diametor; this being the minimum in all cases. The thickness of pipes—an important point—has been fixed on by the commissioners at ¾ inch for 6 inches diameter; 1 inch for 9 inches; and 1½ inch thick for 12 inches diameter.

Great care is required in properly joining the pipes, so as to prevent leakage. The joints are of various kinds, and are cemented with Roman cement or with puddled clay. Underground work of this kind is very apt to be *scamped*, as it is called, and workmen require more than ordinary supervision. If the pipes are not properly bedded, they are liable to break, and either cause a complete stoppage, or soak the soil with the sewage.

In every system of sewerage, a certain amount of continuous fall is of course necessary—the greater the better. The descent of the water is the moving power; and the filth is better carried off the more abundant the supply of water and the more rapid the current. All the sullage-water of domestic operations should be delivered into the sewers, and not allowed to escape otherwise into the soil. The operation of *flushing* consists in fixing in the sewers gates or sluices, which, when closed, cause the ordinary flow of water to accumulate above them; and when a sufficient quantity is collected, they are thrown open, and the rush of water so caused is sufficient to sweep off the deposits.

One of the most important points connected with house-drains is, how to prevent the foul air, generated in them and in the street-sewers, from entering the house. This is the object of what are called *stench-traps*. One form of this contrivance is that known as the *bell*-trap, usually placed over a sink for admitting surface-water into a drain below. A metal vessel, represented in section in fig. 5, has a cover, *aa*, perforated with holes, to the under side of which is attached a bell or inverted cup, *b*. A tube, *d*, communicating with the drain, rises partly within the bell; and when water pours through the covering, and rises to the level of the tube at *cc*, it escapes into the drain; while foul air rising through *d*, is retained by *b*, and cannot escape without forcing itself through the water and under the edge of the bell—which it will only do under pressure. The *syphon*-trap, fig. 6, is also much used: *d* is the basin of a water-closet, connected with the tubular drain *a*, by the pipe *bb*. On this pipe, below the floor-line, *e*, there is a bend, *c*, which always retains a portion of water, and cuts off the entrance of air from the empty part of the tube.

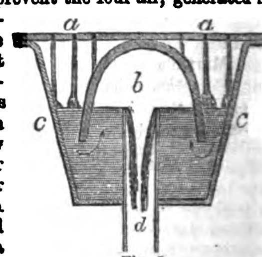

Fig. 5.

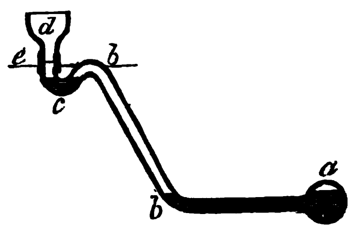

Fig. 6.

But it has been too much forgotten that these traps are efficient only when the air in the drains and pipes is under no extra pressure—a condition which is often wanting. In fact, whenever any part of the pipe or drain below the trap is filled with water, as represented in fig. 6, there must be a regurgitation of foul air into the house every time that water flows down the pipe *bb*; for the pent-up air must escape some way, and it is easier to force its way through *c*, than in the other direction. Any extraordinary rush of water into a drain—above all, the operation of flushing the street-sewers—causes the resistance of the stench-traps to give way, and forces poisonous gases into the houses. To remedy this evil, drains require to be ventilated—that is, to have communications made with the external atmosphere, wherever the air in them is liable to become pent up. This point has been sadly overlooked. The following is the recommendation of the General Board of Health: 'Whenever a water-closet, even with the best sort of water-trap, is introduced into a house, it will be well to provide an escape into the outer air. When several soil-pans or sinks from the apartments of a large house are discharged into a common soil-pipe or vertical main, the main should be continued up to the roof, and opened to the air, and, if practicable, it

should be carried near the chimney. Pipe-sewers must also have ample ventilation provided at all available points. If the air is confined, it is most dangerous when it breaks forth, which sooner or later it will do.'

In towns where there is a proper system of sewers, the house-drainage is of course conducted to the common sewer; there should be no intermediate place of deposit, as a cess-pool. In no case, and under no plea whatever, should these pits of poison and pestilence be permitted. Let them lie open in any degree—and it is impossible to have them hermetically sealed—and they are for ever giving off their noisome and noxious exhalations: they saturate the adjacent soil with their offensive contents; and there is no possibility of preventing the evil without the constantly recurring expense and annoyance of emptying them. The rudest open gutter is preferable in comparison; for it is sure to force itself upon the attention, while the cess-pool, 'out of sight out of mind,' is steaming and fermenting with the most subtile and deadly gases.

In suburban districts, where sewers are not yet constructed, or in the case of isolated houses in the country, the final place of disposal of the drainage-matter must of necessity be some receptacle near to the house. This, however, should never be an open cess-pool, but a closed air-tight liquid-manure tank. The bottom should be an inverted arch, the sides carefully built in, and all the brickwork set in cement—the object being to have it water-tight, so that the liquid may not permeate to the surrounding soil. The cover should be arched, if of brickwork, and provided with a man-hole door as air-tight as possible. A form of sewage-tank on the principle of the upward filter is illustrated in the annexed wood-cut. The drainage enters by the pipe, *c*, into the lower part, *aa*, of the tank, and rises through a false perforated bottom, covered with peat-charcoal, or other absorbent, *ee*, which absorbs part of the fertilising matter; and the liquid is pumped off the top for agricultural or horticultural irrigation. A ton of peat-charcoal is, in a few weeks, transformed into a ton and a half of valuable solid manure, easily removed.

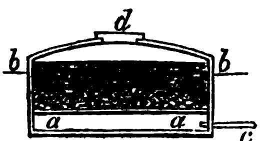

Fig. 7.

How the sewage of towns ought to be disposed of, is a vexed question. Hitherto, the easiest way has been taken—to lead it, namely, into a river or into the sea, and there leave it to shift for itself. But this rough-and-ready plan cannot much longer be tolerated. In the first place, the feeling is growing that our rivers and streams, whose office is to freshen and beautify the country, ought not to be turned to this 'vile service,' which, in populous districts, is rendering them mere abominations. It is questionable, too—if not in law, at all events in morality—whether one town has a right, for the sake of mere economy, to get rid of the nuisance of its own refuse by throwing it into a public river, and thus transferring it to its neighbours below. There is, again, the economical view of the matter. Dirt has been happily defined to be, 'valuable matter in the wrong place;' and it has been proved, again and again, that the sewage of our towns, which does worse than run to waste in our rivers and seas, would, if transferred to the farmer's fields and meadows, be worth millions annually. The question is, how to make this transfer economically and without creating a nuisance. This is one of the most important problems in social economics. Where the situation admits of it, the readiest application of town-sewage is to use it in a liquid state for meadow irrigation. By this means, a tract of several hundred acres of land lying between Edinburgh and the sea, is rendered worth, in some instances, £56 an acre; the grass is often cut nine and ten times a year. At Leicester, Mr Wicksteed, by a process in which he employs cream of lime, separates the fertilising matter of the sewage in a solid form, dismissing the fluid part nearly as pure as the average drinking-water in London. The quantity of dry solid sewage separated in nine months, during the year 1856, was 3000 tons, from three and a half million tons of liquid sewage.

The difficulty of getting rid of the enormous mass of water with which sewage is diluted, is leading an increasing class of sanitary engineers to the opinion, that the refuse-matters of human life ought not to be diluted with water and carried off by sewers, but collected in disinfecting liquids, which would convert them into chemical compounds—inoffensive, and yet valuable as manure. 'As chemistry,' says Mr W. B. Adams, 'has been successful in converting filthy potato-oil and coal-tar into delicate perfumes, it is no doubt chemically possible to convert all the waste material of a household into an innoxious and not unpleasant substance. Two considerations are requisite—first, that it be cheaply done; secondly, that it may not diminish the value of the materials as a manure, by locking up, as it were, the ingredients so firmly as to render them insoluble in the ground for the purposes of vegetation. In this mode, and by no other mode—by chemical conversion, and not by mere mechanical transport—must the ultimate purification of our cities be brought about.'

ABATTOIRS—MARKETS.

The situation and construction of abattoirs or slaughter-houses, and market-places, are intimately connected with the supply and emission of water, and deserve somewhat more than a passing notice.

Abattoirs.—Presuming that every one is less or more acquainted with the operations of the common slaughter-house, it must be evident that these establishments ought to be situated at a distance not only from the denser portions of our towns, but also from the markets or stalls where the meat is exposed for sale; and that they ought, beyond every other place, to be liberally supplied with water. So much filth and garbage of a rapidly decomposing kind is necessarily associated with them, that without an absolute flush of water, and stringent regulations as to its application, they are apt to become centres of the most noisome nuisance and disease. Notwithstanding these facts, which are but too lamentably apparent in all our large towns, yet as a country have we done very little towards the establishment of abattoirs to which the animals might be led quietly, and without danger to the inhabitants, where their carcasses might be dressed with regard to cleanliness, and where the offal might be sluiced away, and collected in such a manner as to become of value to the agriculturist. Our neighbours on the continent are infinitely before us in this respect. The Emperor Napoleon, about the year 1810, ordered five of these establishments to be commenced in different suburbs of Paris; they were executed at the cost of the city, and contained 240 slaughter-houses in all. To each of the abattoirs are attached houses for the melting of tallow; reservoirs, and water laid on by lead pipes wherever required, every means for cleansing, stables and sheds for the use of the butchers, enclosures for the cattle, and apartments for the superintendents. A vaulted sewer receives and carries away all superfluous water; there are also buildings for preparing tripe, &c. The slaughter-houses themselves are formed of walls of wrought-stone, and are sixteen feet wide and thirty-two feet in length. Each has two entrances—one in the yard, by which the animal enters; the other in the outer side, to permit the removal of the meat, &c. Each stall is provided with a supply of water for cleansing, with a drain, and a windlass and pulleys, by which the carcass can be drawn up to be flayed. Other

towns in France have similar abattoirs; and so have Mantua and Brussels.

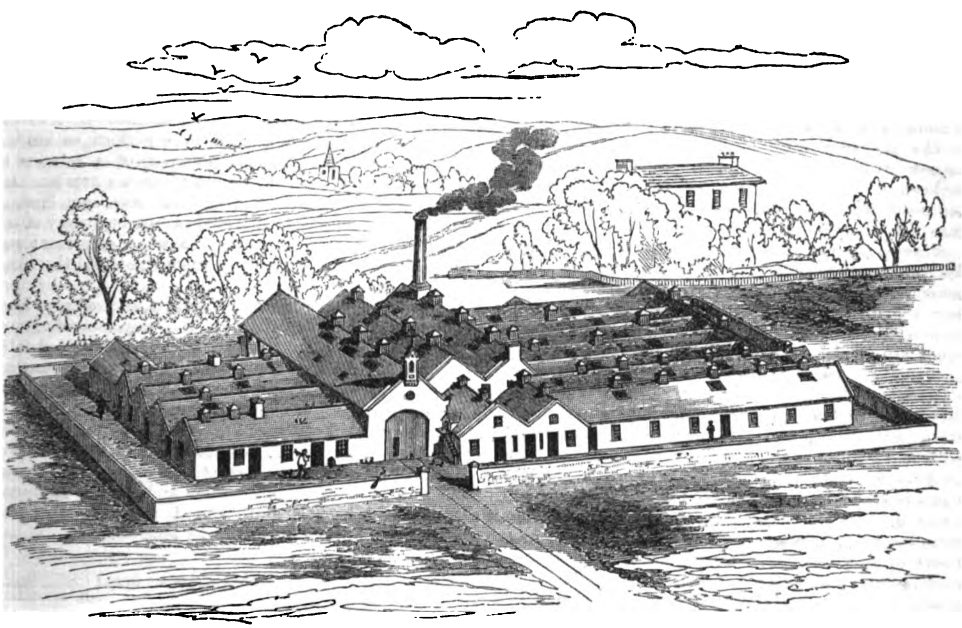
It is much to be wished that some general arrangement like the above were adopted in all our large towns and cities, which at present, so far as the slaughtering of animals and the exposing of their carcasses are concerned, are deficient in the extreme. With the finest animals in the world, the largest consumption of butcher-meat, and every facility for the construction of proper shambles, this department of our economy is conducted in a manner at once obnoxious to health, humanity, and decency. What has been lately effected in London, will presently be noticed.

Markets.—Leaving it for others to decide whether the existing shop-system of our large towns or that of the Oriental bazaar be the more convenient, there can be little doubt that concentrated and commodious market-places for the sale of butcher-meat, fish, poultry, vegetables, fruit, and the like, are highly advantageous for the bulk of the population. Legitimate competition is encouraged, fraud more easily detected, a better choice afforded, and a uniform system of inspection and regulation obtained, which would be utterly impracticable were each country supplier of the raw produce and each town retailer to follow his own isolated plan. Market-places have accordingly been established in all our large towns; but in most cases they are little better than a collection of open stalls, with little regard to arrangement, supply of water, sewerage, shelter, or ventilation. It is true that London, Liverpool, Newcastle, and Aberdeen can boast of commodious, we were about to say magnificent markets; but these are the exceptions, not the rule of the United Kingdom.

Market-places possessing these requisites are common on the continent. Those of Italy—Naples, Florence, Bologna, &c.—are highly spoken of. They are in general lofty airy structures, with light roofs supported on colonnades; have paved areas, are well supplied with water, adorned with fountains, and are easily cleaned. The markets of France are also set down as models, especially the new ones of Paris, in which thorough cleanliness, and a systematic arrangement of the articles exposed, are rigidly enforced. Of our own markets, we have instanced those of London, Newcastle, Liverpool, and Aberdeen, as the most unique and systematic. Those of London are—Covent Garden, for the supply of vegetable produce; Pentonville, for livestock; Leadenhall, for poultry and game; Mark Lane, for corn; Billingsgate, for fish, and the minor depôts of Whitechapel, Newgate, Farringdon, and Hungerford. In illustration of these busy centres, that of Covent Garden may be taken as a fair example. It derives its name from the circumstance of there having once been a convent, with its garden, on the spot which it now occupies. The site of the market, which is spread over two acres of ground, is the property of the Duke of Bedford. Previously to 1830, the booths or stands in the market consisted of rough-looking, slightly built sheds; but in 1828 the legislature interfered, and the present market was built, at an expense of about £50,000; and most ample has been the return received for this money. It is understood that, reckoning rents, and tolls on articles sent to the market, the yearly revenue from Covent Garden market is from £12,000 to £15,000. The rents vary according to the situation of the different shops and stands. Shops in the middle or best part of the market, possessing a little accommodation in the story above, individually bring rents of from £80 to £110 a year. On all wagons, carts, and other vehicles bringing goods to the market, there is toll, varying according to the nature of the articles brought. The open spaces are occupied with various sorts of vegetables, &c., the occupants paying a certain rental per day. This rental varies, according to circumstances and according to situation, from one shilling to fourpence per square foot.

The most recent and important change effected in the markets of the British metropolis has been the formation of the new cattle-market at Pentonville or Copenhagen Fields, in substitution of the very ancient market held in Smithfield since the Norman times. All the numerous improvements wrought at Smithfield failed to render it a fitting locality for a cattle-market in the middle of the vast metropolis; and accordingly, in 1851, an act of parliament was obtained, to enable the corporation to build a new market at the northern margin of London. This establishment, opened in 1855, is unquestionably the finest cattle-market in the British dominions—probably in the world. About seventy-five acres of land were purchased, at a cost of £60,000; and this charge, with the cost of the works and buildings, have raised the total outlay to more than £400,000. About fifteen acres have been appropriated to the market, fifteen to the lairs; and the remainder leaves an ample area for future contingencies. We quote the following from Dodd's *Food of London:* 'The market itself forms a square area, paved throughout with granite, surrounded by a handsome railing with gates, ornamented with a lofty clock-tower in the centre, and provided with an abundant supply of water. In its present state, it could accommodate 36,000 sheep, 6400 bullocks, 1400 calves, and 900 pigs; but whenever it may be needed, increased accommodation may speedily be provided. The area is divided into four nearly equal portions by two broad avenues, crossing each other at the centre; at which point, surrounding the clock-tower, are offices for bankers and others—designated "Bank Buildings." The cattle occupy the eastern sections; the sheep, calves, and pigs are placed in the western. The cattle and sheep pens are conveniently arranged in relation to access and to supply of water; while covered sheds, alongside of which butchers' carts can draw up, are provided for the calves and pigs. Everything that can conduce to the convenience of buyers and sellers, and to the lessening of suffering to the animals, seems to have been thought of by Mr Binning, the city architect. The encircling adjuncts to the market comprise—on the north, two large hotels, with shops on the ground-floor, sheds for the reception of butchers' carts, and a large area of ground available for useful purposes hereafter; on the south, lairs or covered sheds for cattle, *abreuvoirs* or long drinking-troughs, public and private slaughter-houses, and a convenient space for railway approach; on the east, two large taverns, and a space reserved for a hide-market and other purposes; on the west, lairs and abreuvoirs for sheep, and three taverns; lastly, at the extreme south-east and south-west corners are two large spaces available for future slaughter-houses.' At this market, on the great market-day about a fortnight before Christmas in 1855, there were 30,000 head of livestock sold, mostly for consumption on and about Christmas-day.

The slaughter-houses attached to the fine market above described are in all respects well arranged; but they are few in number, and have not yet become a marked feature in the new system. The London slaughter-houses are still, as they have been for many ages, chiefly in the neighbourhoods of Smithfield, Newgate Street, Leadenhall, and Whitechapel: they have undergone improvement, under a licensing act that came into operation in 1856; but they are still, and must be, as long as they remain in such totally unsuitable localities, a disgrace to the British metropolis.



Isometrical View of Covered Homestead.

AGRICULTURE.

MAN is the sole inhabitant of the earth that selects, for the purposes of cultivation, other plants than what the soil naturally brings forth. He has found the earth, in almost every clime, covered with vegetation, yet this often yields little that is fitted to satisfy his wants. The spontaneous growth of nature affording but a limited quantity of food for man, he supplements the supply by capturing the wild animals, which often feed upon what is unsuited for his sustenance. Sometimes, however, the most fertile lands under luxuriant forests, or other natural vegetation, only support a small number of animals. In the most favourable circumstances, a given area of territory cannot maintain many of the human family, so long as they depend upon the natural vegetation or on the chase. It is only after those plants which yield man an abundant supply of food are selected and made the objects of cultivation, that population augments, and civilisation obtains, the primary condition of its existence.

It is therefore one of the chief objects of cultivation to extirpate those plants which naturally occupy the ground, but which do not yield man the particular kind of produce he requires. The earth is covered, in its natural state, by those plants whose habits are best adapted to the climate, and to the chemical and physical nature of the soil. In temperate latitudes, the *cereals*, or corn-bearing grasses, have always been the chief plants from which civilised man has drawn his subsistence. But excepting in a very few spots, none of these are found growing in a wild state. To give full possession of the ground to the cereals, man must wage a perpetual warfare with the indigenous plants which are ever ready to spring up and occupy the ground.

It was a profound observation of Adam Smith, and one that ought to be particularly borne in mind in treating of the *rationale* of agricultural processes, that 'the most important operations of agriculture, seem intended not so much to increase, though they do that too, as to direct the active fertility of nature towards the production of the plants most profitable to man. A field overgrown with briers and brambles may frequently produce as great a quantity of vegetables as the best cultivated vineyard or cornfield. Planting and tillage regulate, more than they animate, the active fertility of nature.' The truth of this proposition is obvious when we reflect, that although there is no ploughing, no manuring, no rotations in the fields of nature, yet vegetation is as luxuriant as in our well-tended cornfields. To yield such results, the plants of nature must possess certain advantages over those which man cultivates. To comprehend the nature of these differences in the requirements of plants, and to enable us more readily to understand the philosophy of the practices of agriculture, the sciences connected with that art will each shortly occupy our attention.

CHEMISTRY OF AGRICULTURE.

The elementary substances occurring in plants, whether wild or cultivated, are oxygen, hydrogen, nitrogen, carbon, sulphur, phosphorus, chlorine, iodine, bromine, fluorine, potassium, sodium, calcium, magnesium, aluminum, silicium, iron, manganese. These eighteen elements are rarely all combined in one plant. It is supposed

that certain of them can be substituted for one another. Thus, sodium and potassium, being somewhat similar in their nature, are sometimes found in varying proportions in the same kinds of plants that have grown on different soils. But the presence of many of them is indispensable, and there can be no substitution in their case. In this position stand the first-named six elements, which play a more fixed part in the economy of vegetation.

The principal mass of all plants is made up of oxygen, hydrogen, nitrogen, and carbon. When a plant is burned, these elements are driven off in the form of gases, and the other elements that had entered into its composition remain as *ash*. It has been customary to call the four elements that disappear by combustion, the *organic elements*, and those that remain in the ash, the *inorganic elements* of plants. But the distinction is without ground. All the elementary substances that are constantly found in a plant, must be considered as necessary parts of its structure or organism, and, in this position, are all equally organic.

With the exception of oxygen, none of the elements found in plants are taken up in the elementary state, but only in a state of chemical combination with other elements. Thus carbon by itself is not food for a plant; it must first be united with oxygen, forming carbonic acid, and in this state it is readily imbibed. Similarly, plants do not take up simple nitrogen, but nitrogen combined with hydrogen, in the shape of ammonia. The substances thus taken up as food by the plant, become united by means of its vital action into definite chemical compounds, called *organic* compounds, because they exist or are formed only in organised beings. Chemists, however, have now very generally adopted the views of Liebig, that the compounds which constitute the food of plants are all inorganic. The inorganic substances, carbonic acid, water, and ammonia, with the alkaline and earthy substances found in the ashes of plants, are now regarded as their only nourishment.

Though plants differ greatly from one another in appearance, and in the physical structure and properties of their substance, yet, when subjected to analysis, they are found to be very similar in composition. The organic compounds of plants may be divided into two great classes—nitrogenous and non-nitrogenous; that is, those which contain nitrogen, and those which are devoid of it.

We know little or nothing of the chemical processes that take place in the interior of plants during their growth. The manner, indeed, in which the particular compounds are determined is still involved in complete mystery. Liebig, however, with his usual sagacity, has pointed out that phosphorus and sulphur are always associated with nitrogenous matter, and that the alkalies and earthy bases direct the formation of substances devoid of nitrogen.

The growth of all plants takes place by the formation of cells, and the nitrogenous structure of cells precedes the non-nitrogenous. In all probability, it is for this reason that phosphates act so favourably on the growth of some plants when applied as manure at an early stage. By phosphates assisting in the formation of the cells of the rootlets of plants, rapid growth is induced. The plants are put in possession of the soil more quickly by obtaining a ready supply of phosphates, and thus obtain the other matters which are fitted for their growth. This chemical point will be more fully treated when we come to other branches of our subject.

The nitrogenous substances found in plants and in animals are usually of the same composition, though they differ in their form. All kinds of wood contain quantities of nitrogenous or albuminous matter, which is identical with the muscle of animals, but most frequently it is not in a fit condition to be assimilated by the larger class of animals. An oak-tree, with its acorns, is composed of nearly the same elements as a ripened plant of wheat. An acre of oaks, too, will often yield, without tillage or manure, as much nourishment for man as an acre of wheat. It was one of Jethro Tull's soundest observations, but which at the same time was entirely against his own theory of vegetable nutrition, that 'men till the ground because tillage procures them better food than acorns.'

It has been truly said by Dr Anderson, that as the analysis of plants has become more perfect, so has the difficulty of explaining the necessity of a rotation of crops, on mere chemical grounds, become greater. Indeed, as already indicated, the fact has been brought out, that not only the cultivated plants, but many of the wild, are composed of nearly the same elements; and as a matter of course, they must feed on the same substances.

The analyses of the ashes of plants by Professor Way, contained in the volumes of the Royal Agricultural Society, put this in a strong light. The subjoined table exhibits the quantity of the alkaline and earthy matters found in an acre's produce each of wheat, turnip, flax, mangel-wurzel, beans, and maize. The wheat-crop is reckoned at 28 bushels of grain and 18 hundredweights of straw; the turnip at 20 tons of bulbs and 4 tons of tops; the flax at 20 bushels seed and 2 tons of straw; the mangel at 20 tons of bulbs and 4 tons tops; the bean at 35 bushels grain and 1 ton of straw; the maize at 48 bushels grain and 1½ tons of straw.

	Wheat.	Turnip.	Flax.	Mangel.	Bean.	Maize.
Silica, . pounds,	84	13·2	22	13	3·17	36
Phosphoric acid, "	20	45·	25	21	16·	31
Sulphuric acid, "	4	50	8	22	3	6
Lime, . . "	8	90	51	21	25	13
Magnesia, . "	6	14	12	22	6	12
Peroxide of iron, "	0	—	9	—	0·69	3
Potash, . . "	22	140	59	133	64·	56
Soda, . . "	2	33	6	70	3	—
Chlor. of sodium, "	—	57	20	160	13	3
	146	442	212	462	144	160

The marked feature in this table, is the large amount of alkalies and alkaline earths that the fallow crops, turnips and mangel-wurzel, require in comparison with wheat. Silica enters largely into the composition of wheat-straw, and only sparingly into other crops. The turnip has more phosphates in a crop of twenty tons than any of the others in the table; still, the beneficial influence which phosphates often have when applied as manure to this crop, must be attributed to other causes than to the mere extra quantity in their composition.

Soils can be fertile only if they contain a supply of alkalies and earthy bases sufficient for the full development of plants. But soils become exhausted for many kinds of plants, even when they contain abundance of these elements. If a vigorous vegetation can be promoted by applying ammonia, it indicates that there is abundance of earthy matter for the wants of the particular vegetation. Some plants are more dependent than others on a supply of carbonic acid and ammonia in the soil. Such differences in the requirements of plants lead us to treat of

THE PHYSIOLOGY OF AGRICULTURE.

Carbonic acid, water, and ammonia, which constitute the chief food of all plants, exist in the atmosphere and in the soil. Plants have the power of obtaining them from both these sources—taking them from the atmosphere by means of their leaves, and from the soil by their roots. Carbonic acid and ammonia become fixed in the leaves of plants by virtue of chemical affinities directed by the vital agencies. Two essential conditions of atmospheric absorption are—first, that the soil supply the requisite quantity of moisture; second, abundance of the substances found in the ashes of plants. These conditions being favourable, the amount of carbonic and

ammonia that a plant will draw from the atmosphere will, other things being equal, depend upon the surface of leaves which it exposes to the air during the growing season. An oak-tree, which has an immense surface of leaves exposed to the atmosphere, has greater facilities of abstracting carbonic acid and ammonia than the wheat or turnip, which must first receive a liberal supply of these substances from the soil, in order to form a surface capable of taking food from the aërial medium.

Plants like wheat and turnips are said, naturally enough, to be great exhausters of the soil, because they cannot be raised unless they are fed or manured by materials yielding an abundant supply of carbonic acid and ammonia. It is now generally admitted that a liberal supply of substances yielding nitrogen is essential for raising a maximum produce of grain and root crops. At the same time, it must be borne in mind that nitrogenous manures have a beneficial influence on all our cultivated crops, but some crops are more dependent on a supply than others, and some can digest or assimilate more in a given time.

The first great physiological distinction which may be drawn with respect to the capabilities of plants for drawing a supply of food from the atmosphere is, that *annuals* are much more dependent on a supply of carbonic acid and ammonia in the soil than *perennials*. Indeed, comparatively speaking, annuals exhaust, but perennials ameliorate the land.

Annuals rarely impart a feature to the natural landscape, for perennial vegetation almost everywhere occupies the ground. Perennials have not everything to do in one season, for every year strengthens their hold upon the soil, and increases the surface of leaves which they expose to the air. Perennial vegetation, therefore, often exhibits considerable luxuriance when the soil is deficient in matters yielding carbonic acid and ammonia. On the other hand, the larger class of annuals are never found growing luxuriantly on soils deficient in substances yielding carbonic acid and ammonia. In fact, annuals must be so far regarded as a sort of parasites. A poor soil may have the effect of causing a perennial to delay the production of its seeds; but through its economical habits, it will thrive where an annual would starve. The thriftless annual casts away its roots and stems, which, as they decay, are liable to be washed out of the soil by the rains. A perennial plant, however, may be said to be manured, and well manured too, by its roots and branches, which are kept in a vital state. The habits of growth in perennials are thus of a very economical character.

It is annual plants that principally supply man with food in the temperate latitudes. Their grand deficiency in having no perennial roots and branches must be made up by manuring. As a general rule in husbandry, if an annual succeed an annual in the rotation, though it may be raised for the purpose of ameliorating the soil, it requires to be liberally manured. Thus all our fallow crops, such as turnips, mangel, beans, and potatoes, are freely treated by substances yielding carbonic acid and ammonia. These crops being all annuals, are particularly dependent on a supply of such substances.

On the other hand, when our fields become exhausted by the growth of cereals, we restore their fertility by abandoning their cultivation for a time, and allowing them to accumulate vegetable matter through the growth of perennials, such as grasses or clovers. Annuals succeeding perennials, perennials succeeding annuals, has been the primitive rotation—when a rotation was necessary—in all countries and in all ages. It was Liebig who first demonstrated, that the effect of pasturing land was, to accumulate ammonia from the atmosphere.

The more nearly that an annual approaches in its habits to a perennial, the less dependent it is upon a supply of carbonic acid and ammonia in the soil. So long as an annual plant puts forth fresh leaves, it is capable of drawing upon the food contained in the atmosphere, and therefore less dependent on a supply furnished to its roots. Thus a pea, which puts forth fresh leaves and blossoms, and even ripens fruit at the same time, can draw more largely from the atmosphere than the wheat-plant, which puts forth no fresh leaves after it flowers, when the most of the leaves lose their vitality. The wheat-plant, being in a great measure devoid of foliaceous surface, must be liberally supplied by manure, and hence it has the character of being an exhausting crop.

As already stated, perennials, as a general rule—particularly true with respect to the larger kinds—are less dependent on a supply of ammonia and carbonic acid in the soil than annuals. Viewing the physiological aspects of the question, the principle may be stated so as to embrace annual and perennial vegetation in the following terms: *Plants are less dependent on a supply of carbonic acid and ammonia in the soil when their vegetative powers coexist, as they do in grasses and clovers, with their flowering and seed-forming processes.*

As was pointed out by Liebig, the atmosphere contains a supply of carbonic acid and ammonia sufficient for all the plants that grow upon the surface of the earth, whether wild or cultivated. This proposition is rendered evident when we reflect that an acre of land under a forest assimilates as much carbon, oxygen, hydrogen, and nitrogen during the growing season, as an acre under any of our crops, such as turnips or clover. It is well to bear in mind, therefore, that the necessity of manuring our fields with substances yielding carbonic acid and ammonia, does not arise so much from a deficiency of those substances in the natural source of supply, the atmosphere, as from an inherent deficiency in the plants cultivated for drawing largely upon this source. The vegetation that covers the surface of the earth in a state of nature, possesses greater facilities for abstracting a supply of carbonic acid and ammonia from the natural source, than most of our cultivated crops, which, consequently, must be manured.

Perennials not only possess greater facilities of abstracting food from the atmosphere, but they have greater facilities of abstracting it from the soil. By forgetting this very obvious principle, great confusion has arisen among agricultural writers respecting the action of some manures. For example, much ingenious speculation has been indulged in to account for the well-known fact, that phosphates have, as a general rule, a more beneficial action on the turnip-crop than on any other. This, however, admits of a simple and consistent explanation, when we reflect that the size of the seed of the turnip is infinitely less in proportion to the space which the plant ultimately occupies, than is the case with any other plant.

The seeds of clover and grasses are small, but as they are thickly sown over the ground, the individual plants do not require to run far in search of phosphates; and they have also more time to search for a supply. With the turnip, it is different; it is sown at a season of the year when vegetation is stimulated by a high temperature. The small seed of the turnip has no phosphates within itself to produce a large growth of leaves and rootlets; and thus, unless it have a liberal supply added as manure, it cannot grow with vigour or rapidity. For this reason, phosphates must often be added to the soil to produce a crop of turnips, when these substances are by no means awanting, and not even deficient in quantity for growing other crops, which must absolutely obtain a supply as large, but whose facilities for obtaining it are much greater, so that they are less dependent on an artificial supply.

A similar rule holds in the application of phosphate to plants as in the application of ammonia. In the case of different plants requiring absolutely the same quantity for their growth, the effect of the application will

be less in proportion to the facilities which each plant has of obtaining it. Perennials are much less dependent on a supply of phosphoric acid than annuals, because, always filling the soil completely with their roots, they are immeasurably better provided, when the growing season arrives, for obtaining a supply than a small seed. We seldom manure our clovers and grasses with phosphates, because, having a net-work of roots through the soil, they can obtain what they require even although the supply may be scanty. When grasses are largely benefited by phosphoric manures, such as bones, it is a sure test of the soil being remarkably deficient in phosphates.

The practical application of these principles, however, will be further illustrated when we come to treat of manuring particular crops. The next theoretical division of our subject is one which has an intimate bearing on the physiology of plants, and also an important influence on the practices of agriculture.

THE METEOROLOGY OF AGRICULTURE.

The proportions of oxygen and nitrogen in the atmosphere are very uniform at all places on the earth, at all heights above its surface, and at all seasons of the year. Dry air contains about 77 parts of nitrogen, 23 of oxygen, and 1000th part of carbonic acid by weight. The atmosphere also contains minute quantities of ammoniacal vapour, which furnishes a supply of nitrogen to plants. Besides these, the vapour of water is always a component of the atmosphere, though it varies more in quantity than any of the others.

The higher the temperature of the air, the more moisture can it hold in an elastic state. The capacity of the air for holding moisture is about doubled for every increase of 20° of temperature on the scale of Fahrenheit. In saturated air, therefore, the proportions of moisture vary with the temperature. At 32°, air cannot contain more than 1-240th part of its weight of vapour; at 52°, 1-120th part; and at 72°, 1-62d part.

There are good grounds for believing that the amount of ammonia in the air is directly as the quantity of moisture it contains. The supply is larger in hot and moist weather, than in cold and dry. This supposition is so far supported by the fact, that all plants are less dependent on a supply of ammonia in the soil in the warm season, than in the cold: in other words, it takes more manure to grow a plant in spring than in summer.

In illustration of this principle, we have only to bear in mind that market-gardeners who force plants early in the season, require to dress their land with the richest manures. Phosphoric manures have no effect on turnips which are sown early in the season, though they are well known to have a very beneficial influence when applied to turnips sown in June. It is therefore certain that plants are less dependent on a supply of ammonia in the soil in summer than in spring. The vivifying influences of a high temperature, have no doubt much to do in giving plants greater vigour to abstract ammonia from the soil; but when all the facts are fully considered, they indicate that the leaves of plants have not only greater powers of absorbing ammonia directly from the atmosphere in warm than in cold weather, but that there is more for them to absorb. There is a numerous array of agricultural facts which appear to admit of no other explanation.

Without going into detail on this subject, we may merely remark, that phosphates have frequently a beneficial effect when applied to all the cereals, legumes, and root crops, when sown late in the season, but without effect when sown early. Their effects, however, are more marked according as the seeds are small, and the size of the full-grown plant is large. For this reason, turnips are more grateful for a supply of phosphates than any other plant which the farmer raises. But barley and oats, when sown in May, are frequently largely benefited by phosphates on the same soils where they would not be benefited by the same application if sown in March. The theoretical dictum which has been put forward by English writers, 'phosphates for turnips, and ammonia for corn,' has led to much misconception regarding the facts involved. If it be necessary to draw distinctions on this head with respect to the requirements of annual plants—always bearing in mind the qualifications we have made—it is pretty near the truth to say, '*ammonia for spring, and phosphates for summer*.'

Keeping in view the principles that have been so far illustrated, we shall, in approaching the more practical subjects, now touch upon the

PHYSICAL CONDITION OF SOILS.

This is one of the most important elements that determine the natural distribution of plants over the surface of the earth. To maintain plants in a healthy growing state, they must obtain a certain supply of moisture from the soil. Plants require different amounts of moisture from this source, as some evaporate a larger quantity of water from their leaves than others. The capacity which soils have of retaining the rains which fall, or of absorbing moisture from the atmosphere, has thus a great influence on their fertility.

In a state of nature, we find plants that require little moisture for their healthy growth, take possession of barren sands; while those that require a larger amount, fix upon soils which are more absorbent or retentive of moisture. The habits of plants, in regard to their necessity for moisture, and the physical conditions of soils, thus determine the character of the natural vegetation that covers the ground.

The agriculturist must often endeavour, however, to make all varieties of soil fitted for growing the particular crops that are most in demand. As his art advances, and his resources become more numerous, the mechanical condition of soils is more under his command, and he strives to give the different varieties such treatment as will fit them for growing all kinds of plants, irrespective of their physical characters.

Tillage, or other means of disintegrating and pulverising the soil, has the effect of rendering it more absorbent of moisture. It thus so far compensates for a larger fall of rain, and tends to maintain plants in a healthy growing state, without which they cannot work up the carbonic acid, ammonia, and other materials that they find in the soil and atmosphere. Tillage, however, is more particularly useful as a means of putting annual plants in possession of the soil, and of causing the organic matter which it contains to decay. Many perennial plants are not benefited by tillage, and most are independent of it. Thus, all our ameliorating crops, such as grasses and clovers, receive no cultivation, and produce as much vegetable matter as those that do.

This fact is rendered still more apparent by viewing what takes place in the forest, where the roots of the trees obtain a greater supply of moisture from the shade which the leaves afford. The shade of the forest is the natural substitute for the absorption of moisture that takes place in a well-tilled field. For instance, the natural habit of the vine is to have its roots fixed in the cool shade of the forest, where it grows without tillage or manure; but the cultivated plant, by being placed in conditions which are at variance with its natural habits, requires careful cultivation.

Forgetting the natural habits of the vine, Jethro Tull founded his theory of the nutrition of plants upon the beneficial effects which tillage had upon its growth. According to him, the food of plants was 'earth,' and 'earth' alone, which only required to be sufficiently divided by cultivation, to allow it to pass into their vessels. In the case of the vine, however, the good

effects of tillage are owing to its rendering the soil more absorbent of moisture, and affording some compensation for the shade which its roots obtain when growing in its natural state. Jethro Tull might have perceived, as clearly as Adam Smith did, that 'a field overgrown with briers and brambles may frequently produce as great a quantity of vegetables as the best cultivated vineyard or cornfield.'

Agriculturists classify the particular physical conditions of soils under the following general heads: sandy, gravelly, clayey, chalky, alluvial, and loamy.

Sandy soils, containing a large percentage of silicious matter, are often unfruitful, owing to the shallow-rooted plants being readily scorched during warm weather. Many of our sand-downs in the vicinity of the sea are of this character, and hence they are more profitable when allowed to remain covered by the grasses which are natural to them. These soils cannot absorb much moisture from the air, nor retain what falls as rain. Sandy soils are most productive in moist seasons or in moist climates. Sir Humphry Davy found that the coarsest and most barren soils, when dried at 212°, absorbed least moisture in a given time. The lowest in the scale of absorbing capabilities was a soil from Bagshot Heath, 1000 grains of which only gained three grains in an hour, exposed to air at the temperature of 62°, saturated with moisture.

Gravelly soils derive their name from resting on gravel. They are usually sandy in their character, and contain pebbles and boulders; but being liable to be scorched by draughts, their produce is variable.

Sandy loams contain a larger proportion of vegetable matter than the above, and thus being more absorbent of moisture, are better fitted for maintaining plants in healthy conditions. Sandy loams are benefited more than any other class by tillage, which increases their absorbing powers. These qualities fit them especially for turnip-husbandry. So also in America, the sandy loams are well suited for maize and its culture in summer. Deep cultivation, more especially in dry climates, is a most important means of increasing the retentive and absorbent qualities of light soils. The benefits of cultivation are apparent from the fact, that grasses on sandy loams are liable to be scorched by the droughts of summer to a greater degree than the turnips in a well-tilled field.

Clayey soils, if they contain little vegetable matter, are the most difficult class to cultivate. Unless they are managed so as to allow the frost of winter to assist in their pulverisation, it is often a most difficult matter to effect this by all the implements at the command of the farmer. Drainage, however, has done a great deal towards rendering this class more easily cultivated; and at present, they are made to produce excellent green crops in ordinary years. Clover and artificial grasses produce heavy crops of hay on clay soils, but the pasture is generally inferior, as the treading of stock seems to be adverse to the healthy growth of grasses on these soils.

Chalky soils have a large proportion of calcareous matter in their composition. The valleys of the chalk districts in England, however, usually abound in clay, and the soil is particularly tenacious. The chalk-loams are well suited for the growth of all kinds of crops, more especially of wheat, barley, clover, and turnips. These are the only soils upon which saintfoin and lucerne thrive.

Alluvial soils are composed of the finest particles of earth which have been washed by floods from the upper part of the courses of rivers. They have generally a rich level surface, and being deep, yield excellent crops of wheat, oats, barley, beans, potatoes, and clover. To manage these lands well, the farmer must undergo a thorough training, so as to enable him to cultivate them with the least expenditure of labour, consistent with giving to the crops those conditions fitted for promoting their vigorous growth. A celebrated soil from Ormiston, in East Lothian, which contained more than half its weight of finely divided matter, absorbed, in Sir Humphry Davy's experiments, six times more water than the soil from Bagshot Heath.

Loamy soils are of great variety, for the term *loam* is one of the most indefinite in agricultural language. Loam may be generally described as a mixture of sand, clay, and vegetable mould, moderately cohesive, less tenacious than clay, and more so than sand. These qualities render them suited for all kinds of crops, which are raised with greater certainty than upon any others.

Varieties of soils, however, are as numerous as the rocks from which they have been formed. The adaptation of the different varieties of soil for the growth of particular crops, will be best illustrated when we come to consider the culture of the particular crops. In the meantime, we shall notice what may be called

THE CHEMICAL CONDITION OF SOILS.

In nature, we find the earth covered by a vegetation that thrives upon the same spots for ages. But it is well known, that if some of our cultivated crops are frequently repeated on the same soils, they become a prey to different kinds of diseases. In nature, those plants which are fitted to the chemical condition of the soil, take possession of it; but man endeavours to make certain plants grow upon every variety of soil.

It is well known that saintfoin and lucerne will not thrive upon land, unless it contains a large quantity of calcareous matter. Now, the analysis of the ashes of these plants does not indicate that either of them requires more lime for building up its vegetable structure, than some others that thrive upon soils containing but a small quantity of calcareous matter. Turnips, it is well known, are subject to finger-and-toe, a disease for which a liberal application of lime to the soil will act as a preventive. That the lime in this case, however, does not act by merely affording lime as a constituent to the crop, is evident from the fact, that it does not cure finger-and-toe when applied, like other manures, at the time the crop is sown. It must be applied for a year or two previous, that it may have time to produce a certain chemical effect upon the land. The particular action in this case, we have been led to believe, consists in the lime directing or controlling the particular decomposition that all vegetable matter is undergoing in the soil. The particular products that an unlimed soil often yields, interfere with the healthy action of the absorbing powers of the roots of plants, which are thereby prevented from taking up a due supply of the earthy matters. The deficiency of these matters induces a corrupt state of the vegetable juices, which thus become the *nidus* for particular kinds of insects. It has always appeared to us that the insects are not the cause of the disease of finger-and-toe or anbury, as Professor Buckman supposes, but a consequence of diseased conditions.

Vegetable physiologists who suppose that plants absorb their food mechanically along with water, are evidently at fault. The process is apparently a chemical one, similar to that which takes place when leaves absorb carbonic acid and ammonia from the atmosphere. But, more than this, we have long been led to the conclusion, before being aware of Gazzeri's experiments, that roots virtually exercise, by their contact with solid matter, an incontestable action in imparting solubility to it. The recent experiments of Professor Way, when rightly considered, seem to render this view more probable. They indicate that the rains have little power to wash out of the soil certain constituents that form the food of plants; unless the roots, therefore, had the power of imparting solubility, these substances could not find their way into the structure of plants in sufficient quantity for promoting rapid growth.

In order that the roots of plants may exercise on the substances constituting their food an absorbent action, which is equivalent to a power of selection, they must be placed in a medium capable of maintaining their healthy functions. That special conditions are necessary to the growth of some plants, is patent to all in the case of the particular kinds which grow in fresh and in stagnant water, in soils abounding in acids, and in others abounding in alkaline earths.

This peculiar chemical condition of soils, which is a quality over and above the mere presence of the constituents of plants, is a highly important one. Finger-and-toe in turnips, clover-sickness, the dying out of certain grasses in particular soils, and many phenomena in the vegetable world, arrange themselves for elucidation under this head.

The particular quality of soils also, which practical men distinguish by the terms 'sharp' and 'deaf,' arises from their chemical condition. It ought to be borne in mind that the repetition of a particular crop on any soil does not necessarily unfit the soil for producing it in a healthy state, if the chemical conditions are favourable. In many soils deficient in calcareous matter, the quantity of crude vegetable matter which turnips leave by their decaying roots, impairs the healthy functions of their roots when too frequently repeated. Lime cures this quality of the land, by correcting or neutralising the decomposing matters left in the soil. One of the most interesting facts elicited by Mr Lawes in his experiments at Rothamsted is, that he has raised turnips on the same land with superphosphate of lime for eight or ten years in succession. The American farmers also sow clover every other year, but do not complain of clover-sickness. Clover-sickness and finger-and-toe, however, sometimes arise from an actual deficiency in the soil of the substances found in the ashes of the plants. Without going into the practical illustration by which we have been guided on this question, we have said enough to shew the importance of the chemical conditions of soils, in explaining some of the facts of agriculture.

CLIMATE OF GREAT BRITAIN.

Our space being necessarily limited, the effects of climate on crops and systems of farming will be best treated when considering the culture of particular crops, and the practical economy of rotations. Under the present head, we shall confine ourselves to some general remarks on temperature, rains, and evaporation.

However useful the *means* of monthly temperature may be for some purposes, they are of little use for illustrating the effects of climate on crops. It is obvious that the *mean* daily temperatures give a very inadequate idea of the character of the weather of any day. The mean may be made up by a wide range of temperature, or the reverse. Thus, a mean of 60° may be made up of a maximum of 75° and minimum of 45°, or a maximum of 65° and a minimum of 55°. Such atmospheric conditions, however, would be attended with different effects on the soil and plants. Did our space permit, we would shew that the mean maxima and mean minima temperatures put us in possession of data to estimate the effects and intensity of many climatological influences. The following are the mean maxima and mean minima temperatures in the different months at a few stations:

Temperature.

More rain falls on the west coast than the east; but it is worthy of observation that the excess is principally confined to winter and autumn. In the eastern counties of England, most rain falls during the warm months, but the evaporation being great, the climate is then dry.

From these tables, the distinguishing peculiarities of climate in different parts of the British Islands are apparent. The warmer nights and cooler days of Cornwall give as high a *mean* as the cooler nights and warmer days in Middlesex. Even when the fall of rain is the same at two places, the effects of this different composition are very marked upon crops, inasmuch as the range of temperature determines to a considerable extent the force of evaporation.

The drying or evaporating power of the atmosphere is also an important matter to be attended to. The range of the thermometer is less on mountains than in valleys, and, consequently, corn is always more difficult to harvest on high grounds, owing to the diminished force of evaporation. (See METEOROLOGY.)

CULTIVATION.

One of the principal objects of cultivation is to uproot and destroy all plants but those that the farmer desires to rear. No implement has been found to effect this so well, and at the same time so economically, as the plough, which Mr Mechi has facetiously termed 'an undertaker and grave-digger.' It ought to be borne in mind that it is of quite as much importance to have the grasses in a field of pasture completely buried, as to have the land thoroughly pulverised. The pulverising of the land, though it has the effect of rendering it more absorbent of moisture, is chiefly useful for the purpose of allowing plants readily to take possession of it. In this matter, the same principles in a measure apply as in manuring. The smaller the seeds of vegetables, the quicker their growth, and the larger the full-grown plants; so much the more careful and perfect must the preparation of the ground be. Thus, it is well known that the turnip requires a better tilth than other crops.

The plough no doubt at first sight appears a very simple implement; nevertheless, upon no one has there been so much mechanical skill expended, in rendering it adapted to different varieties of soil. In ploughing, an important principle must be steadily kept in view—that clay or tenacious soils should never be ploughed when either too wet or too dry. In ploughing the first time for fallow or green crops, it is of importance to begin immediately after harvest, or as soon after wheat-sowing as possible, in order that strong tenacious soils may have the full benefit of the frost. On wet stiff soils, frost acts as a most powerful agent in pulverising the earth: it expands the moisture, which, requiring more space, puts the particles of earth out of their place, and renders the soil loose and friable. On such soils there is no rule of husbandry more essential than to open them as early as possible before the winter frosts set in. If left till spring, clay-soils may be too wet for ploughing; or if the season be dry, the earth, when turned up, will be in hard clods, very unfit for vegetation. Therefore, on farms having a proportion of clay and of light soils, it is necessary that the strong wet land should be ploughed first, provided the weather will allow.

Ploughs.*

From the time when animal power was first applied to the cultivation of the soil, an implement of various form has been used for the purposes of a plough. In primitive times, it usually consisted of a piece of bent wood, attached to which was a broad share, either hardened in the fire, or faced with iron, a single handle, and no mould-board, or rest; and in those regions where the burning sun destroys the surface-matting of turf, such a simple instrument may still be used. But the requirements of modern agriculture have called forth an implement of greater power and perfection of form. A hundred years have not elapsed since the only plough in use in Scotland was rude, cumbrous, unwieldy, and usually drawn by eight oxen. When horses were attached to it, a lighter form was required; and after rural improvements began to spread, James Small, a Scotch plough-wright, had the merit, of changing its form, and adapting it to the wants of the time. He duly proportioned the several parts, and fitted the coulter and share to cut, and the mould-board to raise and turn, a rectangular-shaped furrow, at a much less expenditure of force, and with greater precision than had ever been done before. For many years, this was almost the only plough used in Scotland. Wilkie of Uddingston, having formed all the parts of the implement of iron, made some alterations

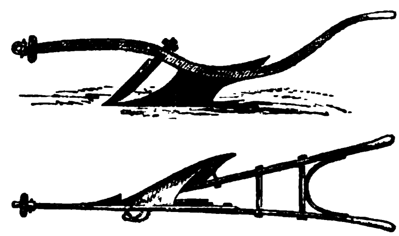

Fig. 1.—Swing-plough.

upon the set of the coulter and share, and also on the form of the mould-board, so that on thin clay-soils narrower furrows might be produced, with a greater shoulder or apex than the rather plain flat work which characterised Small's plough. With various slight alterations by different makers, until thorough-draining changed the texture of the soil, there was little improvement effected upon this implement. But since then, various alterations have been made both in England and Scotland. Ponton in West Lothian, and Sellars, Huntly, are the most recent improvers of the swing-plough. The first-named maker constructs his with long convex mould-boards, and irons set to cut high; Sellars, again, has the long mould, but his are plain cutting ploughs. Mr Finlayson, Bridge of Allan, has recently attached a couple of wheels to the common plough, by which all the regularity and equality of

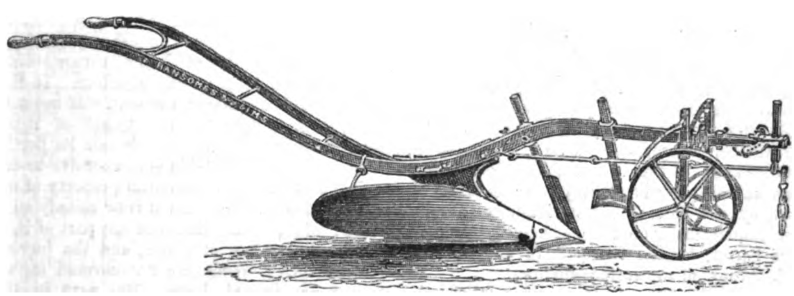

Fig. 2.—Ransomes' Wheel-plough.

the English wheel-ploughs are attained; the wheels can be detached, and the implement again used as a swing-plough. In England, wheels had been in use from a remote period; and there the spirit of improvement took advantage of these to construct an implement capable of making excellent work, with the assistance of little skill in the workman. In Scotland, most of the improvements implied the existence of great skill in the ploughman; and the result has been that in such hands the Scotch swing-plough is able to produce any description of work, while that of the English wheel-plough is always the same. Ransomes of Ipswich has

* For the following remarks upon ploughs, grubbers, and harrows, we are indebted to Mr Melvin, Bonnington, Ratho, who has devoted much attention to the principles upon which they are constructed; the portion on agriculture generally, is by Mr R. Russell of Kilwhiss, Fife; and the remaining section on spade husbandry and the culture of waste lands, has been prepared by Mr J. Clarke of Long Sutton, Lincolnshire.

the merit of originating several improvements on the wheel-plough, and his latest form is represented, fig. 2. During the last ten years, not a few makers have been keenly contesting for the merit of constructing the implement that produces the finest work at the least cost of power. Mr Howard has been tolerably successful: his plough somewhat resembles the above; and Mr Busby of Bedale, with the assistance of Mr Oathwaite, contrived very beautiful mould-boards, which were held first at the Exhibition in 1851. For several soils we prefer his plough to others; although Mr Ransomes, with his last improvement, has again taken the lead. None of these very beautiful implements please the Scotch farmer in ploughing lea, as they turn the furrow rather flat over; but they unite in a high degree those contrivances which go far to make up for the guiding-hand of man. They have long finely shaped mould-boards, rather short broad shares, straight coulters, and with the two wheels on level land, can almost move unattended. It is difficult to lay off land into ridges with them, and drilling cannot be done, neither do they answer for the mode of ploughing which is called *gathering* in Scotland, as the space which is left when the last furrows are taken out, is very broad; and they don't make the neat close finish that the swing-plough, when well handled, does. It may almost be said that, with the wheel-plough, it is the plough that does the work; with the swing, it is the man. It is not necessary here to enter upon any full examination of the principles upon which the various ploughs are constructed. In Scotland, they may be divided into two classes—the first follow Small's model, and are what are called plain cutting implements; the other, Wilkie's, which are capable of both plain and high-shouldered work. In England, all the ploughs we have seen, cut plain—that is, raise and lay the furrow at an angle of about 45°. After the land became drained, considerable difficulty was felt with the concave moulds, from their not throwing the soil cleanly off; and to amend this, a longer and more convex form was adopted. These are now coming into general use.

Trench Ploughs are either worked with three or four horses, and are constructed on the same principle as the plain cutting common ploughs, but with all the parts larger and stronger. The ploughs constructed by the Marquis of Tweeddale for this purpose, unite to a certain extent the properties of the subsoil and trench plough. Although they have been before the public eight or ten years, and have succeeded well at Yester, as yet their adoption has not become general. (See figs. 25, 26.)

The Subsoil Plough is now less heard of than it once was. Although the theoretical principle on which the operation of subsoiling is founded, is undoubtedly correct, and although the implement, as improved, effects the breaking up of the subsoil thoroughly, yet the effects visible from its use are frequently not so great as to induce those who most hopefully commenced with it, to continue further operations. Read's, as improved by Slight, Edinburgh, is the steadiest and best implement. Some subsoil-ploughs of very light construction can be drawn by two horses; but in ordinary subsoils, the stronger implement cannot be effectually wrought without four horses, besides the pair in the common plough which throws off the surface-furrow.

Hitherto, the application of *steam-power* to ploughing has been more in the way of experiment than of useful work. Where stationary engines have been used, a great loss is sustained in transmitting the power to a distance; and where locomotive power has been applied, a like loss has to be met in overcoming the resistance of the soft yielding surface-soil. Although high authorities are of a contrary opinion, it appears to be impossible to apply locomotive-power without resorting to a more solid surface than that of the soil, and unless part of the weight of the engine be supported on the firm subsoil, it is not easy to see where this support can be had. Resting on the surface-soil, the slightest shower so clogs the machine that it comes to a stand. This cause alone, in an uncertain climate, would operate greatly against its usefulness, even though it could be profitably wrought.

Ploughing.

The usual dimensions of the furrow-slice in lea or in hay stubble, are eight or nine inches in breadth, by six in depth. In stubble for green crop, the breadth may be ten inches, by seven or eight in depth; and the force of traction amounts to between three and a half and four and a half hundredweights. The extent of land ploughed per day, by a man and pair of horses, depends on the soil, and the breadth and depth of the furrow. During the winter months, three-fourths of an imperial acre is the average amount gone over; but with the lengthening day, or in cross-ploughing, more can be done. There are three modes in which land is chiefly ploughed; the first, and once most common, is called

Gathering.—The usual breadth of a ridge being taken as eighteen feet, the ploughman sets up a line of poles along the middle of the first ridge. The poles are made nine feet long, for the purpose of measuring the distance from the edge of the field, at which they are to be set up. Along the line so formed, he drives his plough, throwing out a furrow; and after reaching the further headland, turns his horses to the left, and throws out another in the same line. He then returns back both of these furrows so thrown out, along with a portion of firm soil; and he may go on adding furrow to furrow on either side of the first two, until the space is gone over. In practice, it is found more correct to leave the outer half of the first ridge unploughed, and to plough the second half of the first ridge and the first of the next. In doing this, the ploughman is said to wind out the space, which means turning his horses always to the left.

Cleaving just reverses the positions of the furrows previously gathered. The ploughman begins where he formerly finished, and winds out each ridge by itself.

Casting is now by far the most common method of ploughing land. The ploughman proceeds to set up poles eighteen feet from the side of the field. Along this line he throws out two furrows right and left, returns them again, and ploughs round these until thirty-six feet have been gone over; forming thus two ridges. He then measures a space of fifty-four feet from the last-drawn furrow, or seventy-two feet from his first-drawn line; again sets up his poles, ploughing other thirty-six feet there, and leaving a space of thirty-six feet between the two first-ploughed pairs. This space, forming two ridges, he now proceeds to wind out, turning always to the left, instead of to the right as before. In this way, any breadth of land may be wrought. It must be borne in mind, that the longer the length of ridge, and the fewer turnings, the more work can be performed; and that angular-shaped fields are expensive to cultivate.

The first and most essential property of every plough is, that it shall throw the furrow cleanly off the mould-board; when earth adheres to any part of it, the friction thereby causes loss of power, and the furrow is imperfectly turned; weeds are not covered in, and the old surface not turned down. The next is, that it shall leave the furrow in that position that exposes the greatest amount of soil to the action of the air; and also, that the furrow so turned over, while preserving that shape, shall be so rent internally by the action of the irons in cutting and raising it, that the air and frost may be enabled most easily to penetrate its substance. If, then, we are right in this position, either very long or very short mould-boards are objectionable: the last from breaking up too much the shape; and the other from polishing off too smoothly the exposed surface. The action of the plough on the soil is not so effectual as that

of the spade, from the spitfuls being all separately cut. But the amount of surface which a well-turned furrow presents to the air, is much greater than what any digging can throw up; and hence the advantage of having the furrows continually broken by frequent rents, and these openings not plastered up by a long mould-board, as is done in some of the more recent forms of plough, which compress and smooth the furrow after it has been fairly put in its place.

In the construction of ploughs, strength must never be sacrificed to lightness; a stone or two more weight is often of use in heavy soils; and the beam, head, and stilts must be thoroughly stiff and unyielding, when under the pressure of the horses and man, in the soil. A well-constructed plough should never be touched by the ploughman, either with the screw-driver or hammer. The share and coulter are the only parts he has control over.

A form of plough, known as the *turn-wrest*, is much used in Kent, and is highly thought of by the farmers there, as admirably adapted for clearing the land from grass, &c., as well as for loosening the soil. It is capable of being used for a variety of purposes. A view of it as improved by Mr Smart of Rainham, and manufactured by Ransomes and Sims of Ipswich, is given in fig. 3. The turn-wrest plough lays the furrows all in

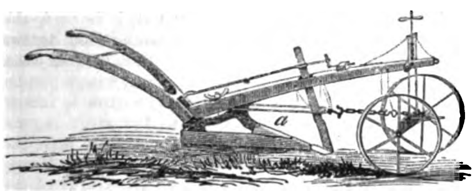

Fig. 3.—Smart's Turn-wrest Plough.

one direction from one side of the field to the other; this being effected by the wrest *a*, which acts as the mould-board of the ordinary plough, and by a very simple mechanism can be changed from one side of the plough to the other—'so that either becomes alternately the mould-board as the furrow requires to be turned.'

Grubbers

are now much more in use than formerly, the soil being more open and easily penetrated by their teeth. It is often far more advantageous simply to loosen up the soil than turn it over. Especially since green crops have been extensively grown on clays, this implement is almost essential, as thereby the disadvantages of a spring-furrow are dispensed with. The upper portion of the soil, loosened and ameliorated by the winter's frost, not being turned down, still allows the drill-plough to form an open, friable ridgelet for the seed. In the cleaning of land, this implement is also most advantageous; and we know of nothing better for this purpose than an improved Scoular or Kirkwood grubber, with two wheels about two and a half feet in diameter, and the teeth proportionally long. They not only work the land most effectually, but never clog, as those with wheels of smaller diameter do; and when tested along with the one-wheeled Tennant's or Scoular's, are infinitely superior. On sloping land, when crossing the slope, a one-wheeled instrument works very imperfectly. Much of the bad odour into which grubbing has fallen in some places, has arisen from the use of imperfect implements, or from the want of properly trimming them; but it must always be borne in mind that surface-weeds are not removed by grubbing. Where these abound, and are troublesome, there is nothing like the plough for destroying them. The quantity of land which a two-horse implement will go over in a day, is generally four times the quantity which the same team could plough. In Scotland, the grubbers chiefly in use are Tennant's and Scoular's one-wheeled ones, and Scoular's and Kirkwood's three-wheeled implements. In England, there are, under the name of Cultivator, Coleman's and Johnston's, Bentall's Broadshare, Ducie's Drag, &c., all of which are more complicated and heavy, with more cast iron in their construction than those in Scotland; but they work well when sufficient horse-power is applied to them.

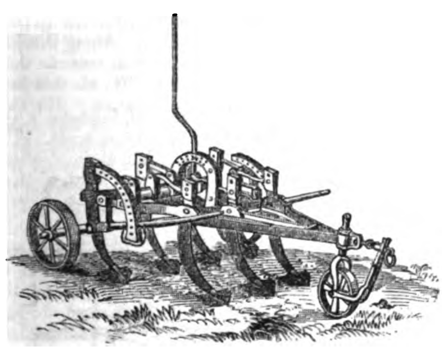

Fig. 4.—Coleman's Cultivator.

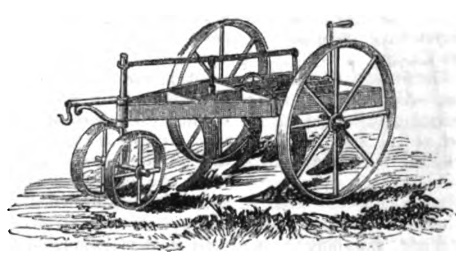

Fig. 5.—Ducie Drag.

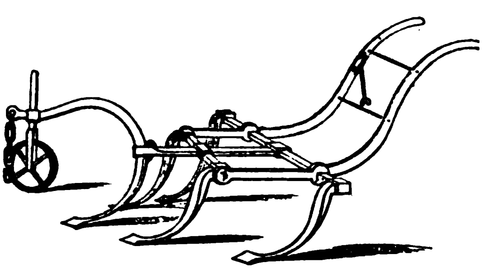

Fig. 6.—Tennant's Grubber.

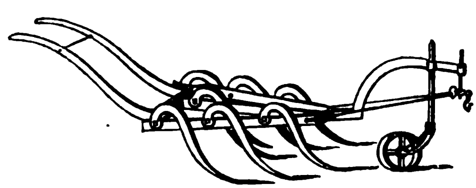

Fig. 7.—Scoular's Grubber.

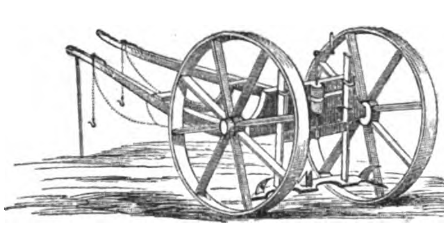

Fig. 8.—Johnston's Skim Cultivator.

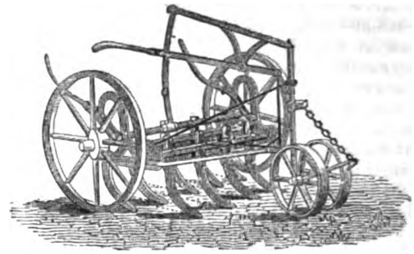

Fig. 9.—Biddell's Scarifier.

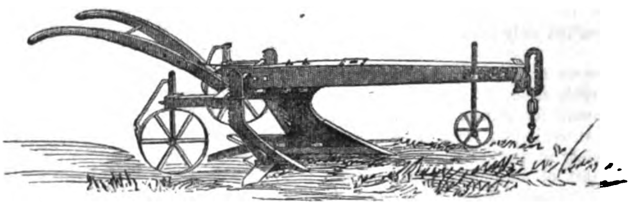

Fig. 10.—Bentall's Broadshare.

We believe that more attention to the action in the soil of this implement would result in the construction of still greater improvements than have hitherto been effected. It has never been determined what form of tooth is best—some advocating a diamond-shaped point; others, a broad chisel; and others, a duck-foot shape. We prefer, after many trials, a broad chisel point, four inches at least, which, with the bend upwards, works the soil very effectually, but requires considerable force.

Harrows.

The early form of harrow was that of a board of wood with wooden pins fixed in it. Iron then took the place of wood for these teeth; and at length it was found that a framework of wood, consisting of *slots* and *bulls*—to use the language of the joiner—into which iron tines were driven, made a more effective implement. These harrows were generally made of a square form, and one was allotted to each horse. By making these of a rhomboidal shape, and coupling two together, and attaching a long tree to them, as in fig. 11, the irregular action on the soil of the former kinds was avoided, and each tooth operated on a separate portion of soil and at an equal distance from the one next it, as shewn in the dotted lines.

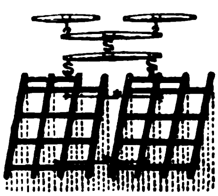

Fig. 11.

These harrows have for long been made entirely of iron, and are very effective on several sorts of land; but not so on all, as there is too great rigidity about them, and they do not adapt themselves to any slight irregularity of surface, so that a more pliant implement was required. This, to a certain extent, was found in the Bedford harrow, originally constructed in three divisions, and containing seventy-two teeth, being thirty-two more than in the common harrow. The first formation of these Bedford harrows has been changed by introducing joints into the separate connections, and thus a far more pliant, though necessarily weaker implement has been produced, as shewn in fig. 12. These harrows work admirably in the same line as the furrow; but in crossing they are apt to pull back the closing furrows of the ridges; and on newly ploughed or stiff lea-ground they are objectionable on this account. They are heavier to draw than the common kind, and do not shake out the quicken roots or couch-grass very freely when the land is being cleaned: on this account, it is preferable always to have both sorts on the farm. The Bedford harrow costs about £1 more than the rhomboidal. Other

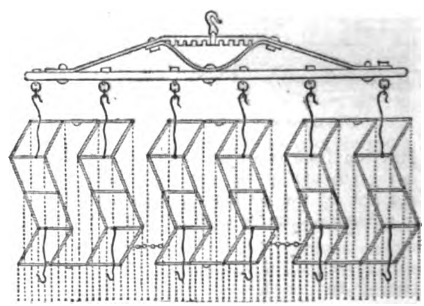

Fig. 12.—Howard's Harrow.

forms have been introduced. Smith of Deanston's web-harrow was well fitted for covering grass-seeds. That form represented in fig. 13, is another attempt at progress, for in the implements hitherto described, whatever amount of motion may exist between the separate

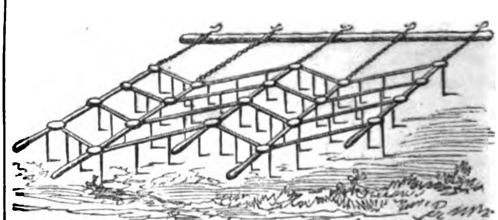

Fig. 13.—Coleman's Diagonal.

harrows, the distance between the teeth remains the same. But in that figure an attempt is made to have the space between the teeth altered at will, so that coarse or fine work may be made. All harrows are now made to cover a space of nine feet, and are drawn by one pair of horses. In ten hours, about sixteen imperial acres can be gone once over. As it is often necessary to go from four to seven times over the same ground before the surface can be made sufficiently fine, it would seem advisable to have an implement, covering a narrower

space, but more effective, so as to save several of these repeated journeys.

There is a useful article called a *drill-harrow*, for cleaning and lowering down bean and potato drills. This implement consists of two parts, each of which fits over the top of the drill, and, being concave on the under surface, acts on the top and sides. It is drawn by one horse, and is very effective.

Other sorts of harrows there are for the purpose of cleaning the intervals between the rows of green crop; but these are now less used, the horse-hoe being made to do much of the work to which they were applied.

The Norwegian harrow is an implement which is much used in some localities; and as it can be wrought in showery weather, when it is impossible to have rollers going, it has advantages which commend its use. It acts more in the way of cutting than compressing, and is also preferred on this account.

The roller and *clod-crusher* are implements that cannot be dispensed with on any farm. The smooth iron roller is too well known to require any description;

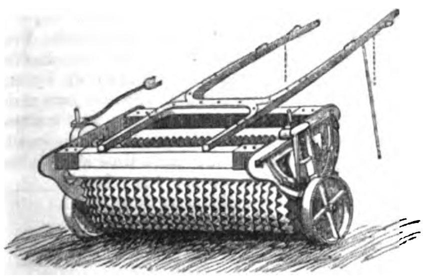

Fig. 14.—Crosskill's Clod-crusher.

and Crosskill's clod-crusher is now generally acknowledged to be a very efficient implement for strong clay lands.

Carts.—Two kinds of machines are in use for conveying produce to market and other purposes in husbandry—wagons and carts—and of these there are several varieties. Wagons with four wheels, and drawn by two or more horses, are acknowledged to be best adapted for conveying great loads to a great distance, and that is their principal merit. For all ordinary purposes connected with husbandry, the one-horse cart with two wheels is preferable.

The Scotch cart, as it is called, is a most convenient and useful machine; and to add to its uses, it may be rendered serviceable for carting hay or straw by placing a movable frame on its sides, as represented here. The Scotch cart (without the frame) is suited for conveying any kind of material—dung, turnips, grain in sacks, &c.—and usually carries from eighteen to twenty-two hundredweights, when drawn by only one horse; with a horse in trace, the weight may be augmented. In Scotland, all grain for market is carried in these one-horse carts, and to any distance. On such occasions, one driver can take charge of two carts.

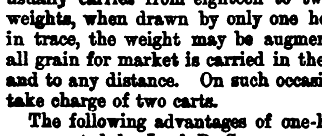

Fig. 15.

The following advantages of one-horse carts are well enumerated by Lord R. Seymour. 'A horse, when he acts singly, will do half as much more work as when he acts in conjunction with another; that is to say, that two horses will, separately, do as much work as three conjunctively: this arises, in the first place, from the single horse being so near the load he draws; and in the next place, from the point or line of draught being so much below his breast, it being usual to make the wheels of single-horse carts low. A horse harnessed singly has nothing but his load to contend with; whereas, when he draws in conjunction with another, he is generally embarrassed by some difference of rate, the horse behind or before him moving quicker or slower than himself; he is likewise frequently inconvenienced by the greater or less height of his neighbour: these considerations give a decided advantage to the single-horse cart. The very great ease with which a low cart is filled may be added; as a man may load it, with the help of a long-handled shovel or fork, by means of his hands only; whereas, in order to fill a higher cart, not only the man's back, but his arms and whole person, must be exerted.' To these just observations it need only be added, that in many parts of England there is a wasteful expenditure in horse-power, a couple of horses being often set to draw a clumsy wagon to market, containing a load which could with the greatest ease be drawn by one horse in a less ponderous machine.

Every well-conducted farm establishment is now, or ought to be, provided with a variety of small but useful machines—for slicing turnips or potatoes, chopping hay or pease straw, bruising beans, pease, or oats, weighing-machine, &c.—all which, of the newest construction, are to be seen at the establishments of agricultural implement-makers. Utensils for cooking food for cattle, dairy utensils, and tools for manual labour, need not here be particularised.

SOWING.

In Scotland, the greater part of the cereals are sown broadcast. In England, on the other hand, they are frequently sown by drilling-machines; indeed, in the eastern counties, they are almost all sown by machinery. Experience has hitherto seemed to shew that the benefits of drilling are more marked in poor soils than in rich, on light than heavy land, in dry climates than in moist.

At the same time, it was not to be expected that drilling by machines should be so much followed in Scotland, owing to the hilly and irregular nature of its surface. It gained a footing, however, pretty early in East Lothian, and we believe that the practice is still slowly extending.

Drilling is less advantageous in the case of late-sown spring crops, which grow up more rapidly, and keep down weeds. Up to a comparatively recent period, late sowing of cereals was very common in Scotland, and experiments on the drilling of these crops were not generally favourable. It is attended with greater benefits in early-sown spring crops, such as wheat and chevalier barley. On light and inferior soils, it is almost essential to the raising of these crops with any degree of certainty. This also applies to autumn-sown wheat on such soils.

The drilling of cereals effects a saving of seed, for if they are sown broadcast, more grain must be used, to prevent weeds springing up. In drilling, also, the seeds are deposited at an equal depth, and fewer of them are destroyed. When drilling has been adopted in Scotland, it has no doubt been customary to sow too much seed, a practice that should be avoided, as the crowding of the plants in rows stunts their growth, and renders the crops less productive. But the effects of using too little seed must likewise be guarded against, as this prolongs the life of the plants, causing them to tiller and produce more vascular stems, which are longer in ripening, and the quality of grain is inferior. Late-sown spring crops, therefore, should have a more liberal quantity of seed than early. On land in good condition, it is safer to sow two bushels of barley to the acre in the early part of March, than three by the middle of May.

It is also of importance to keep in mind that the land requires to be more carefully prepared in spring,

when the grain is drilled. The roots of the plants being nearer to the surface, are more liable to be influenced by the drought, unless the comminution of the soil is carefully accomplished

There are various kinds of machines for sowing grain. The English implement-makers have brought them to far more perfection than the Scotch. In the English machines, the seed is lifted from the box by cups attached to a barrel driven from the axle of the large wheels. The cups, emptying themselves into small hoppers communicating with the coulters by tubes, seem to be best adapted for effecting a regular flow of seed. The coulters, also, which form a bed for the seed, being jointed, move up and down, and permit of a uniform pressure, and, consequently, of an equality of depth at which the seed is deposited. This important principle of jointed coulters has only been recently introduced into the Scotch drills. The following sketch represents one of Garrett's corn-drills, which are in general use in the eastern counties of England.

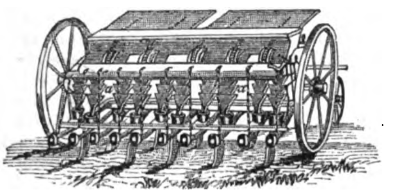

Fig. 16.—Garrett's Corn-drill.

One of the most important advantages of drilling cereals is the facility which it affords for keeping the crops free from annual weeds. In fact, the farmer has a much greater command over his crop when it is drilled than when it is sown broadcast. Weeds can be much more cheaply extirpated by the hoe than by pulling them by the hand. The great improvements that have recently been made in horse-hoes have rendered these implements of great service to the cleaning of drilled grain-crops. The following engraving represents Garrett's horse-hoe, which, though somewhat

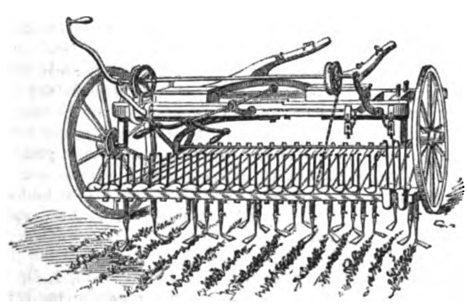

Fig. 17.—Garrett's Horse-hoe.

heavy, is otherwise a most efficient implement. The foresteerage should be attached instead of the shafts, as it is thereby rendered easily managed.

DRAINAGE.

The vast amount of capital which has been expended in drainage within a quarter of a century, attests its utility and necessity. Before the introduction of furrow-draining, stiff and tenacious clays were of comparatively little value. They were cultivated at much expenditure of labour, and the crops which grew upon them were influenced to a great extent by the variations of the seasons. A system by which wet and worthless land could be rendered dry and valuable, was an improvement so patent to practical men, that we need not wonder at the efforts which have been made to effect this end.

Drainage by open ditches was no doubt the first mode of freeing land from superfluous water. The Roman agricultural writers mention the good results arising from covered drains, which were formed of wood and other substances, which served so far to render the land dry. More than a century ago, a large extent of clay-land was drained at narrow intervals in Norfolk and Essex, by putting in brushwood and even straw in the bottom of the drains. The progress of this operation, which is now regarded in many soils as essential to economic culture, was slow and partial, until Mr Smith of Deanston reduced the practice to a system, and shewed the principles upon which its efficiency depended. Through the exertions of this advocate, furrow-draining soon became a *sine quâ non* in the culture of clay-soils.

The great majority of practical men consider the line of greatest fall, or quickest descent, as the best for cutting drains in a field. This, it may be remarked, is also usually the direction for ploughing the land and forming the ridges; so that the drains are commonly put into the *furrows*, and hence the distinguishing appellation, *furrow-draining*. The smaller drains are conducted into larger or *main* drains, instead of each discharging its quota of water into the open ditch. This is rendered necessary, as the mouths of the smaller drains would be more liable to be choked up by the growth of weeds; while the collecting of water into main drains secures a fuller flow to sweep out any matters which might accumulate where the discharge was small.

The most efficient, and at the same time cheaply cut drain, is one represented at fig. 18. It is made so that a pipe of a cylindrical form may be laid along its bottom, which should be of no greater width than what is necessary to its being securely placed.

Fig. 18.

Drains of this form are cut with a set of spades which are of different widths—the broader being used for taking out the top, and the narrowest for the bottom. The one which cuts the last spit is called the *bottoming tool*, and its introduction has effected a considerable saving in cutting drains.

Before the general use of pipes, stones were the common materials with which drains were formed. Mr Smith recommended that they should be broken so small that they might pass through a ring two inches and a half in diameter. From nine inches to a foot in depth was the quantity which was commonly put in. This was found to be a most efficient way of making drains; but unless the stones could be gathered from the fields, or quarried in the neighbourhood where they were used, an immense amount of labour was involved in filling them.

When tiles and pipes were first used, it was even thought necessary to have some gravel, or small stones, placed above them in the drains, for the purpose of enabling the water to find its way into them, as seen at fig. 19. It was soon found, however, that tile-drains were quite as efficient without any stones or gravel; and that they were less liable to be choked up, as the clay or earth acted as a filter in preventing the intrusion of any kind of solid matter.

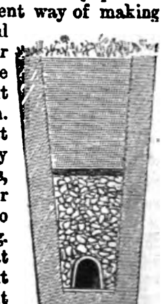

Fig. 19.

Many kinds of tiles and pipes have been tried, but the cylindrical form is now most used. At one time, a bore in the tile of an inch in diameter was thought sufficient, but two-inch tiles are now preferred. They are usually made about fifteen inches in length. The continuity of the drain is maintained completely by *collars*, which should always be used as a means for securing efficiency and permanency.

Much discussion has taken place in regard to the proper depth of drains, as well as the distance at

which they should be placed. Mr Smith at first advocated the making of drains from two and a half to three feet deep, and at intervals of from ten to forty feet, according to the nature of the land. Experience, however, has been gradually favouring deeper drains, at wider intervals. Mr Parkes went the length of recommending a depth of from four to six feet, at intervals of from twenty-four to sixty-six feet. If the deep drainage of land which this distinguished engineer has advocated cannot be successfully carried out in all cases, the graphic manner in which he has described his own experience, and illustrated the principles of draining, has been productive of good results. Even on the most tenacious soils with subsoils of *till*, few now think of having drains less than three feet in depth, though the distance apart should not in many cases be more than from fifteen to eighteen feet.

The mere tenacity of clays is not the element which determines the depth of drains, or the distance at which they should be placed apart. It is now well understood that the success of draining by pipes depends upon the fissures which are produced in the subsoil by the droughts of summer never entirely closing up; and thus minute channels are formed and lead the water into the drains. The coarse tenacious clays which are to be found in the chalk-valleys of England, *crack* readily by the droughts, and form deep fissures, which render them comparatively easily drained. On the other hand, in the moist climate of Scotland, the subsoils which are of *till* are long in cracking; and the drains in such land should not be so deep, and at shorter distances apart. As the properties of clays become better understood and classified, practical men will soon come to be more at one in regard to this important point connected with the economy of drainage.

The principal advantages of drainage are, the deepening of the staple soil and rendering it more friable, so that a superfluity of water which would cause the formation of those chemical compounds that are found in stagnant water, is prevented. The greater depth of mould, and more perfect culture, render the soil more absorbent of moisture in dry periods of weather. As crops can usually be sown sooner on drained lands, they also ripen earlier, and produce more abundantly. In short, while drained land obtains a greater capacity for moisture and manure, it imparts to plants greater capabilities for economically working up the materials which they find both in the soil and atmosphere, seeing they are maintained in the most healthy conditions of growth.

Green Crops.

Grasses, as seen in perfection in rich lawns or meadows, are the most beautiful crops that grow. The constant carpet of verdure which these present in England, is owing to the great number of varieties which come to perfection at different periods of the year. In sowing out fields for permanent pasture, we do well to take a lesson from nature, and sow a mixture of grasses which are valuable, and at the same time indigenous to the soil; for although those grasses which are best suited to the soil, will often, in a series of years, take possession of it, yet time is gained by anticipating nature.

The common varieties of annual and perennial rye-grass are sown when the land is under a system of rotation, and when the fields only remain for one or two years in pasture. These are valuable plants in all the moister parts of the British Islands, but in the south-eastern parts of England they yield little leaf; and the droughts encourage the production of stems which are not relished by stock. For this reason, less benefit is derived from two years of pasture in England than in Scotland.

Italian rye-grass is now grown to a considerable extent in Britain: it is not a good pasture-plant, however, as it grows thin upon the ground, and being shallow-rooted, does not thrive, unless the soil is shaded by its own leaves, which in some measure perform the same ends as pulverising the soil, and rendering it more absorbent of moisture. A liberal dressing of manure in early spring, by sending up a mass of vegetation, which protects the soil from the evaporating influences of the weather, renders the crop less dependent on a supply of rain. Italian rye-grass, for this and other reasons, is better adapted for cutting than for pasturing. It is grateful for liberal treatment, as no other cultivated plant seems to have greater capacities of growth.

Grasses being usually sown out with a grain crop, grow little for a year; their roots have time to run through the soil in search of the earthy matters which the crop requires. Phosphates are therefore seldom used for grass, unless the soil is very deficient of these substances. Nitrogenous manures are thus best suited for all descriptions of grasses.

Clovers grow most freely upon calcareous soils. In the rich marly loams of France, the various varieties of red clover produce fine crops, though much more frequently sown than in Britain. On the limestone gravels of America, red clover is sown every other year, and the land shews no symptoms of clover-sickness. It is on the non-calcareous formations of Scotland that we find this plant so uncertain and fickle in its growth. This we attribute to the want of calcareous matter to correct the vegetable accumulations which take place in the soil, and interfere with the healthy functions of the roots.

Clovers, like grasses, are most benefited by nitrogenous matter, if the soil is favourable to the healthy functions of their roots. A rich dressing of farm-yard manure will sometimes so far counteract clover-sickness by affording the crops a ready supply of earthy matter, which they cannot otherwise absorb, to carry on the assimilating processes in a healthy state. We have known instances of a dressing of two hundredweights of guano, applied to an acre of young clover layers in autumn, after the corn-crop was removed, impart such a vigour to the plants, that they grew luxuriantly next summer, while the clover entirely disappeared from the rest of the field. From the roots of clover running deeper into the ground, nitrogenous manures are most advantageously applied in autumn, as they tend to strengthen the plants, and enable them better to withstand the deleterious conditions by which they are sometimes surrounded.

From red clover sending its roots deeply into the ground, it is comparatively independent of moisture in dry climates. The same observation applies to saintfoin and lucerne, which are invaluable crops in southern latitudes where the soil is calcareous. All these plants, like grasses, maintain a large surface of fresh leaves exposed to the atmosphere, and therefore restore to the soil a supply of vegetable matter, when it has been wasted by tillage.

Beans are only grown on the first-class land in Britain. This arises from the crop requiring a deep soil into which it can send its long tap-roots, and obtain the necessary supply of moisture for its large surface of leaves exposed to the atmosphere. Being an annual, and sown early, it must have a full supply of manure, unless the soil is very rich. The most approved plan of raising this crop in Scotland is to sow in drills or ridges, twenty-seven inches apart, into which an allowance of farm-yard manure has been placed. The common allowance of seed to the acre is four bushels. By this means, the crop can be so cultivated as to permit of the land being cleaned during the growth of the crop.

The bean has a tendency to grow too much straw on the west coast, with comparatively little grain. On the other hand, the extreme heats of the south of England are apt to stunt its growth and induce diseased conditions, which are followed by attacks of insects. The common bean is perhaps as sure a crop and as abundant in its produce on some of the rich lands in East Lothian, as in any part of the island.

Peas are greater favourites in warm and dry districts than in wet and cold ones, where they are more difficult to harvest. They are frequently sown along with beans; but they do not occupy an important place in the rotations of well-cultivated districts, since the general introduction of turnips.

Turnips, for the feeding of stock, arrive at great perfection in this climate. Being sown, however, in that part of the rotation which was formerly occupied with a bare fallow, they form a most expensive crop. In fact, it is not only designed that they should answer all the ends of a bare fallow, but through their growth, and by being usually consumed by stock, an accumulation of vegetable matter takes place on the farm. By this means, a larger quantity of the more valuable produce, such as cereals, may be raised and disposed of.

Turnips are divided into various classes, in each of which there are several varieties. The Swedes, belonging to the most valuable class, have been largely cultivated since the introduction of light manures. White turnips are sown in Scotland early in season; but in England they are usually put in very late. Yellow turnips are the principal class raised in Scotland, as they seem better suited to the low temperature.

In the south of England, Swedes are sown from the end of May to the 1st of July; so late sowing, however, is only practised on light soils. White turnips are sometimes sown there so late as the 1st of August. Swedes and white-globe turnips are sown in Scotland from the 1st of May to the 10th of June; and all the yellow turnips should be put in ten days after the latter date.

The land should be thoroughly cleaned and pulverised before turnips are sown. It is usually drawn up, by the double-moulded plough, into drills or ridges, about twenty-seven inches apart, into which the manure is spread. The manure being covered by 'splitting' the ridges by the plough, the seed is sown by machine on their crests. This enables the young plants to obtain a ready supply of manure, which promotes a rapid growth. When the leaves are about two inches high, Tennant's grubber should be used betwixt the rows; and thinning may then be commenced. This is done by hand-hoes; and the work being light, it is frequently performed by women and boys. Three expert hoers may go over an acre a day. The crops are frequently drill-horse hoed or grubbed during their growth. Earthing up the turnips by the plough is less frequently practised than formerly, excepting upon stiff clay-soils.

To raise maximum crops of turnips, the soil must not only be well cultivated, but highly manured. All those varieties which are early sown should be most liberally dressed with matters yielding carbonic acid and ammonia, for the simple reason, that the longer a plant lives, the more it can digest and assimilate; and further, all those varieties whose growth is extended over the longest period, should have the manure supplied in the most carbonaceous form, which is the best means of slowly yielding up the active elements as the crops require them. Farm-yard manure is best adapted for prolonging the growth of turnips in autumn; and their early growth is best promoted by guano and other soluble nitrogenous manures.

Phosphoric manures are largely and efficaciously employed in raising late-sown turnips. Except on rich soil, these manures can never be relied upon to raise *maximum* crops of turnips, which require more ammonia to do so than any of the cereals. It ought to be borne in mind, however, that in nineteen cases out of twenty in which phosphates are beneficially applied to the turnips, there is really abundance of phosphoric acid diffused through the soil; the necessity of an artificial supply is owing to the small seeds of the turnip requiring a concentrated dose placed within reach of their rootlets, so as to promote their rapid development. Phosphates enable the turnip-plant to form roots and leaves, without which it can neither appropriate the nutrient matters existing in the soil or the atmosphere. Medium crops of turnips may often be got by dressing with superphosphate of lime, in the middle of June in Scotland, when the crops have little time to grow; but this manure, unless combined with matters yielding ammonia, cannot be relied upon to raise a crop of turnips which is sown in the middle of May.

Turnips are either consumed by sheep on the fields in which they grow, in grass-fields, in fold-yards, or feeding-houses. In the vicinity of large towns, they are sold to cow-feeders. This department of agriculture will be treated in CATTLE AND DAIRY HUSBANDRY.

After having the roots and leaves cut off, the bulbs of the turnips are usually stored in heaps about eight feet in width, and piled up as high as they will lie on this breadth of base. They are covered with straw, which is fixed on with ropes, or sometimes a spadeful of earth is thrown on, to prevent the wind blowing it off. Earth, however, is so far objectionable, as it prevents the gases from escaping, and encourages fermentation. The most common error is putting too great a quantity of turnips together, for the heap ferments and the roots decay. Perhaps the most simple and best mode of storing turnips, is to lay them out in a field adjoining the farm-steading, in large heaps, level on the top. The only precaution necessary, is not to make the heap more than two feet in depth. A quantity of loose straw is thrown over the top of the heap, which the first shower of rain is sufficient to beat down so as to require no further fastening. When stored in this way, turnips resist the frosts better than when piled up in pits, which are more exposed to the wind; and they are also less liable to sprout in spring, as the straw keeps them moist and cool. In storing turnips which are to be early consumed, care must be taken not to cart them in when in a frozen state, or covered with hoar-frost.

Mangel-wurzel.—The productive powers of the Swede are more limited in England than Scotland, or, in other words, larger crops can be grown in the latter. Any deficiencies, however, which exist in the root-growing capabilities of the southern climate with respect to turnips, are amply made up by its adaptation to the growth of mangel-wurzel.

The plant having small seeds, and being sown nearly two months earlier than the Swede, must be liberally supplied with manures yielding phosphates and ammonia. With the exception of Italian rye-grass, or the cabbage, no other plant is capable of working up or assimilating a greater quantity of food in a season. The capacity of the mangel for manure is seen when planted on the richest garden-ground, or on spots from which dunghills have been removed. In these circumstances, turnips will only grow to leaves and stems, while mangel will produce large roots. In highly manured land in the south of England, very large crops of mangel are raised, far outweighing the produce of Swedes in this country.

Mangel-wurzel is an inferior plant to the Swede in the climate of Scotland, for, even with the most liberal treatment, the crops are comparatively light. In our colder climate, also, the plants have a much greater tendency to seed than in the south. In the inferior produce of the mangel, and this tendency of the plants to seed, the effects of the lower temperature of Scotland are more clearly exhibited than by any other cultivated crop.

One of the chief elements that hasten the seeding of plants, is a scanty supply of food. The growth of the cabbage, for instance, in its leafy state, is only protracted by a liberal allowance of manure. Indeed, the abnormal supply of food that vegetables obtain in their cultivated condition, is the principal influence which alters their habits of growth. Liberal manuring, and a soil of good physical capacity, are well known to have the effect of protracting the period of bulbing in

turnips; while the opposite conditions, light manuring and a dry soil, cause the plants to flower.

It is only a modification of the same principle that we have stated above that is in operation, when mangel flowers in summer in colder climates. Plants, like animals, may be starved by cold as well as by a want of food. A want of moisture, also, has the effect of making vegetables form flowers. Dry and cold weather, conjoined with a short allowance of manure, have a great influence in hastening the seeding of plants.

Plants, as formerly pointed out, are more independent of a supply of food to their roots in summer than in spring, owing to their facilities for abstracting food from the atmosphere being greater in the one season than the other. The healthy functions of mangel-wurzel can only be carried on at a higher temperature than what is necessary for the turnip. To delay its seeding when the temperature is low, it must be supplied with a greater quantity of manures in a more concentrated state. Thus, mangel is not so liable to flower in Scotland when it grows upon the spots from which dunghills have been removed; neither do those who dress the plant with large quantities of liquid manure have occasion to complain of flowering. So, in warmer climates, the increased vitality of the plant, by making it less dependent on an extra supply of manure, retards the flowering process. At the same time, if the plant is under-manured, it will seed in warm as well as in cold climates. The principle of a higher temperature delaying the period of flowering in plants, is strikingly exhibited in the case of our cereals, inasmuch as wheat, barley, oats, and rye, have no tendency to seed when sown in summer in southern latitudes.

Potatoes usually enter into the rotation on farms where they can be easily sent to market. Being a bulky article, however, they cannot bear in ordinary years the cost of transport for a great distance by carts. It is in the neighbourhood of large towns, therefore, that they are prominent crops in the rotation. The usual period of planting in the British Islands is from the 1st of March to the middle of May, and of harvesting, October and November. It is customary to plant eyesets, or cut pieces of potato, each having an *eye* or point of germination. They are planted at a distance of eighteen inches apart in drill-furrows (made by the double mould-board plough), previously well dressed with farm-yard manure or guano. After the plants appear above ground, they are as frequently grubbed, earthed up, and hand-hoed, as may be required to keep the ground loose and free from weeds. The disease which so generally attacked this crop in 1845, has, by its repeated appearance, rendered it precarious. Being very susceptible of frosts, potatoes must be stored carefully in pits covered with straw and earth.

White Crops.

Wheat is the most important of all the cereals, and we believe it grows over a wider range of latitude than any other plant. In Egypt, it is raised in the very centre of the Tropic of Cancer, and on the continent of Europe as high as the 60th parallel. It is right to observe, however, that this extreme range is obtained by its growing in the one country in summer, and in the other in winter. Indeed, it is not a plant that requires a high mean temperature before it puts forth its ears; it even exhibits little tendency to produce seeds if sown during the heats of summer in France or America.

In Britain, a great number of varieties of wheat are cultivated. Spalding, Kessingland, Lammas, Burwell, red wheats, are great favourites in the dry climate of England, as they yield more grain than any of the white varieties. The farmers consider that they are usually as well paid by the larger quantity of grain, though the quality is inferior. Hopetoun, Hunter, red chaff white, red strawed white, and Fenton, are the most common varieties cultivated in all parts of Britain. April or awny wheat is largely sown on inferior soils in Scotland, where it is quite as sure a crop as barley, and the straw is as good for fodder.

From six pecks to two bushels of grain are usually sown by the drill in the south of England. Less than the latter quantity is seldom sown in Scotland; and when sown on the common furrow, four bushels is the common allowance after green crops. Spring-wheat should be sown thicker than autumn, to assist in hastening on the crop to maturity, and in promoting a finer sample.

Wheat is generally sown in the southern and eastern counties of England after clover lea. In all dry climates, the decaying matter which clover-roots afford seems to be best adapted for feeding the wheat-plant during the long time it is in the ground. It ought to be constantly borne in mind that, in manuring a plant, we should be guided by similar principles as in feeding an animal. Theoretically speaking, every one must allow that no more food should be supplied to plants or animals than they are capable of daily digesting or assimilating. Manures, therefore, should be of such a nature as to afford nourishment to plants during their whole period of growth. Plants which do not grow rapidly, should be supplied with manures that slowly yield up their active substances. Autumn-sown wheat, therefore, in dry climates is best manured by a clover sod.

As a general rule, the growth of autumn-wheat is most economically promoted by carbonaceous substances; such as clover roots, the refuse of the manures which have been applied to green crops, or by rape cakes, and inferior qualities of guano, which only yield up their ammonia during the growth of the crop.

With spring-sown wheat, a different course must be followed. Its growth being more rapid, the ammonia should be in a form that can be more readily assimilated, and hence Peruvian guano is the best application for this crop. The most soluble manures, on the other hand, such as nitrate of soda, are best fitted for top-dressing wheat in spring, for the rapidity of growth which ensues in early summer enables plants to digest a larger quantity of food in a given time.

The value of manures is rated by the quantity of ammonia (or nitrogen) which they contain. But so much is this principle held in abeyance to the *form* in which this element exists in manures, that even before the recent rise in the price of guano, nitrate of soda was largely used for top-dressing wheat, though nitrogen in this form cost the farmer double the price per pound that it did in Peruvian guano. Rapid growth and soluble manures must go together; for this reason, inferior guanos, which yield up their nitrogen more slowly, are preferable, for autumn dressings, to Peruvian, in which the ammonia is in a more soluble form.

In all hot countries, the common varieties of wheat can only be sown with advantage in winter; even in the eastern counties of England, where the range of the thermometer is considerable in May, these varieties do not succeed so well when sown in spring as they do in Scotland and the western counties of England. Thus Mr Read, in his excellent report on the farming of South Wales, in the *Journal of the Royal Agricultural Society*, says: 'Spring-wheat flourishes well in this climate, and has been long cultivated with success. Instances of wheat being sown on the 1st of May, and ripening within nine days of barley sown on the same field, and at the same time. An intelligent farmer last year did not finish sowing his wheat till May, and even with that drenching sunless summer, it was cut in the early part of September, and produced thirty-two bushels to the acre.' On the other hand, common wheats yield a small return, even in Suffolk, when sown so late as February.

From the circumstance of the growth of wheat being extended over a longer period than any of the other cereals, and of its growing in a colder season, it must be more liberally manured with substances which

slowly yield up the nitrogen they contain. For this reason, it has always been regarded as a very exhausting crop, requiring more manure than any other. But owing to the fact of the soil requiring to be dressed with substances that only slowly yield up their active principles to the crops, the soil cannot be exhausted by crops of wheat to the same degree as by crops of inferior grains, which require less manure, but which leave less in the soil, and thus really exhaust it more. Turnips grown by market-gardeners require a great deal of manure, and are justly regarded as exhausting crops; but from the large residue of manure left in the soil in the mere forcing of these crops, the land is still left in a richer state than when crops of turnips are grown by superphosphate of lime. Instead of proprietors of land restricting the quantity of wheat on their farms, they would do well to encourage its extension, seeing the growing of wheat is actually a test of the good condition of the soil.

Wheat is liable to certain fungous diseases, as, for example, smut, mildew, and rust. The last two it is not so much in the power of the farmer to prevent as the first; they are more common in England than in Scotland. Early or thick sowing tends to impart conditions which are unfavourable to the appearance of these diseases. Smut is best prevented by watering the wheat with a solution of sulphate of copper—one pound of this substance being sufficient for half a quarter of wheat; it should be dissolved in as much water as will thoroughly wet the grain, which, as soon as dry, may be sown.

Rye is usually grown on light sandy soils, and requires less care than wheat. It is frequently sown along with winter tares in England to be cut for soiling, and when sown on the wheat stubble, is extremely useful as food for breeding flocks in spring, as it comes forward earlier than tares, and affords good pasture when other substances are scarce.

Barley.—There are several varieties of this grain cultivated in Britain: the early English, Annat, Stirlingshire, chevalier, and *bere*, are the most common. This grain grows best upon a rich mellow loam, moderately retentive, where the culture has been careful. It rarely succeeds where the soil is stiff and wet. On the heavy clay-soils of Essex and Suffolk, excellent crops of barley are got after summer fallow. The ground being ploughed up in autumn, the mould which is pulverised by the frosts affords a fine seed-bed. The surface is usually scarified before the seed is sown by drill. An intelligent agriculturist, who farms heavy clay-soils in Suffolk, writes: 'When new year has commenced, the Suffolk plan is never to let a favourable opportunity escape for drilling barley, if the land is prepared.' When land is in good condition, early sowing is to be preferred, as heavier crops and finer quality are thus obtained.

On the light soils of the southern counties of England, barley is usually sown after the turnip-crop, which is generally eaten on the ground by sheep. After the land has been trodden, it must be carefully prepared by two or more ploughings, rollings, and harrowings, to pulverise it, and render it more retentive of moisture. In the dry climate of Norfolk, the farmers expend a great deal more labour in preparing the land after turnips, than they do in the moister climate of Scotland, where turnip-land is rarely ploughed more than once. Owing, also, to the greater heats and droughts in the south of England, good quality of barley is rarely got when sown after the middle of April.

It is much easier to over-manure barley in moist climates than wheat; hence the latter is more frequently sown in the western counties after turnips eaten on the land by sheep. Much land is well adapted for the growth of the finest quality of barley along the east coast of Scotland. Barley is now sown in Scotland as soon as the land is in a fit state to receive the seed. On rich and dry soils, barley is rarely injured by spring-frosts; it is only on weak soils, or such as are out of condition, that complaints of this nature are heard of.

On many of the trap-loams in Scotland, barley is sown after wheat; in this case, it is generally sown late, as the more genial temperature acts as a compensation for a richer soil. This is in accordance with the principles enunciated under the head of the Meteorology of Agriculture. Early-sown barley is best manured by Peruvian guano, as plants growing in the colder season demand a more liberal supply of food. If barley is sown in May, less ammonia should be applied, as at that season the crop can rely to a greater extent upon the atmosphere, if it obtain a ready supply of phosphoric acid. Thus superphosphate of lime is generally of little use when applied to barley sown in March, but has often good effects when sown in the end of April or May.

The six-rowed variety of barley, called *bere*, is now chiefly confined to the northern counties of Scotland. It is the most hardy of all the kinds of barley, and being stiffer in the straw, it is not easily laid by rains or over-luxuriance.

Oats.—Of this grain there are many varieties, which our space prevents us from particularising. The potato-oat is an early and productive variety on low and rich lands; indeed, it has gradually extended as the fields have been better manured. Though the oat is usually considered to thrive best in moist climates, the level land along the sea-coasts of Scotland, such as in the plains of the Lothians, produces the most grain and finest qualities. Many varieties are suited to climates which are too wet and cold for other grains. The oat is a grosser-feeding plant than any of the other cereals, and can be more freely dressed with nitrogenous manures. In the rotation, oats succeed grass or clovers, and in moist climates, leave the land much cleaner than when wheat is sown. From four to five bushels of seed to the acre are sown broadcast, and from three to four when drilled. The usual time of sowing is from the beginning of March to the end of April. If the land be in good condition, the earlier the better.

Haymaking.—When the grass has arrived at or near its full growth, but before the seed is perfected, it should be cut down by the scythe for hay. A short time after being mown, it should be turned over in full swathes, without being scattered. If not in a fit state to be cocked the first day after cutting, it should be put into small handcocks as soon as its state of dryness will allow; from these it should be gathered into larger ones, and when its condition permits, put into tramp-ricks. The gathering of the hay is generally performed by women and boys, some carrying, and others raking

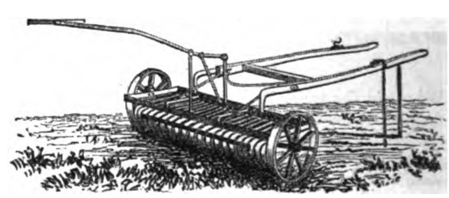

Fig. 20.—Horse-rake.

up what may remain. The horse-rake is now much employed in gathering hay, and from the construction of the teeth, gathers fewer stones or earth than any which has yet been invented. Let it be remembered that the less the hay is exposed to the sun, the better is its flavour and strength. In wet seasons, the utmost care will be required not to stack the hay while moist; for then, like moist sheaves of grain, it will heat, and either burst into a flame, or be seriously damaged in quality. The criterion for good hay is, that it should be greenish in colour, be perfectly dry, and possess a sweet odour and saccharine taste.

REAPING—HARVESTING.

The ripeness of grain is shewn by the straw assuming a golden colour from the bottom of the stem nearly to the ear; or when the ear begins to droop gently, the corn may be cut. Although the straw may be green from the ear for some distance down the stem, yet if it be quite yellow at the bottom, and for some distance upwards, the grain requires no further nourishment from the earth, and if properly harvested, will not shrink. These indications of ripeness may suffice for wheat, barley, and oats. In peaty soils, however, the ears of oats and barley usually ripen before the straw, which often requires to be cut in a green state.

Reaping.—It was formerly the practice to cut grain with a saw-edged sickle; but this has given place to a larger instrument, with a smooth edge like a scythe. The reapers are usually divided into bands of six or seven, with a binder to each band. When the ridges are less than eighteen feet broad, three reapers are usually placed upon each ridge, the middle reaper making the bands with which the sheaves are bound up. When four reapers are placed upon one ridge, as is usually the case when the ridge is eighteen feet broad, two bands are laid upon one ridge; and two binders are enabled in this way to manage twelve reapers, placed on three ridges, stooking the corn all in one row upon the middle ridge. When the crop is very strong, however, it is often found necessary that each binder should stook by himself. In harvesting oats and barley, each shock or stook is formed of ten sheaves placed in two rows, the head of each sheaf leaning upon the opposite one, and a sheaf on the top at each end. They stand usually due north and south, so that each side may receive equal benefit from the sun. The straw of wheat being longer than that of oats and barley, the stooks of the former are made larger, having six sheaves in each row, and one on the top at each end. When the crop is thin, half-stooks are frequently set up; and to forward the drying process, the end-sheaves are now generally omitted when the weather is good; but this should never be done where the climate is uncertain, as it exposes the corn to rain.

Oats and barley are now frequently cut with a scythe, which is either plain or furnished with a bow or cradle, in order to lay the grain evenly in one direction. Wheat is almost universally cut with the sickle; and if the weather keep good after this operation is performed, it will be ready for stacking in the course of five or six days. Barley is frequently cut with the scythe in England, but the sickle is more commonly used in Scotland. Barley and oats require to lie ten or twelve days, as they are more or less mixed with clover, before being ready for stacking. The clover ought to be completely withered before the corn is stacked; and, indeed, it requires the greatest caution on the part of the farmer in ascertaining whether his crops are in a proper state for being carried to the stack-yard. The best way for judging of this is to take out a handful from the centre of the middle sheaf on the lee-side of the stook, repeating this on several parts of the field; and if the knots or joints of this are dry and shrivelled, the crop may be led home in safety. All corn crops should be cut as low as possible, for by this a great addition is made to the straw, and consequently to the future manure.

The process of reaping, either with the sickle or the scythe, is necessarily a tedious one; hence the repeated attempts which have been made to use machinery to expedite it, and relieve the farmer of much anxiety, by enabling him to house his crops with rapidity. It has been matter of surprise to some that machine-reaping has not been generally adopted; but a moment's consideration will shew that there are difficulties in the way which prevent machinery being so easily applied in this as in other departments of farm-practice. Thrashing, for instance, is unvarying, or nearly so, in its operation; the material to be operated upon being generally presented in nearly always the same circumstances. Not so with reaping—the material is continually changing its condition; and the difference between a rainy day and a dry one—between hilly ground and level—is just all the difference that is required to make the material either that which affords facilities to the machine in cutting, or, on the other hand, of throwing such obstacles in the way as to render it almost an impossibility to cut it at all. In view, however, of what has already been effected, and of the increased attention now directed to it on the part of mechanists and agriculturists, we have no doubt that in a short time the difficulties in the way will be removed, and a reaping-machine take its place in the implement-department of every well-managed farm. Since the exhibition of 1851, in London, the reaping of grain by machinery has attracted a great deal of attention. The American reapers, exhibited there, shewed that the mode of cutting the grain might be simplified, though these machines were in a comparatively imperfect state, and not fitted for the requirements of English agriculture. The following wood-cut represents the cutting part of Hussey's reaper. The cutters are set in motion by the machine as it progresses.

Fig. 21.

Bell's original reaper was a much more perfect machine than any of the American machines: as it laid down the corn so that it could be easily gathered up for binding. The liability of the cutting-knives to get out of repair was its principal defect. It was soon discovered, however, that Bell's might be greatly improved by M'Cormack's mode of cutting. A large number of machines have been made on this combination, known as Crosskill's and Bell's reaper. Owing to the great weight of this machine, many makers are striving to manufacture an implement of less weight, and requiring less power. This important point has already been so far attained by Dray's Hussey. The number of ingenious mechanicians who are now directing their attention to the making of reapers, leads us to expect that a still more efficient implement will be produced than any that are at present in use.

Stacking.—When the crop is thoroughly dry, it is led home to the stack-yard on open spar-built carts, and built into stacks so constructed as to afford complete shelter from the weather. The stool or bottom upon which the stack stands was formerly made of loose straw or brushwood; but in the best managed farms, it is now the practice to construct the stacks on stands made of stone or brick, or upon pillars made of stone or cast iron, sparred across with wood or iron. These stands are formed so as to prevent the access of vermin, which is calculated to effect a saving of two bolls in thirty; and many

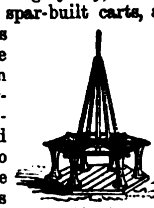

Fig. 22.

have funnels from the top to the bottom of stacks, to admit a free current of air. In Scotland, the stacks being mostly round, a sheaf is first placed on its but-end, in the centre of the bottom or stand; around this, others are placed, also upright, but with a slight inclination of the head inwards, until the stand is nearly filled. The stacker then places a layer of sheaves horizontally on the outside of these, lying on their sides, the ear-ends inwards; and pressing them together with considerable force, he continues to lay on rows until the outside sheaves are as high as those standing on end. The whole stack is filled up in nearly the same manner, the ear-ends of the sheaves being always inwards, with a regular inclination downwards and outwards to their butts, and the centre of the rick being higher, and not so compressed as the outside. Proper attention to the sloping of the sheaves is necessary from the foundation of the stack, but particularly so at the intake of the inner layers, that part being always left more open. When this is done, the stacker sets up an outside circular row of sheaves, having their but-ends projecting a few inches beyond the body of the rick; after which the outside layers come gradually inwards, until the roof is drawn to a narrow circle, when two or three sheaves placed upright completely fill up the stack. The topmost sheaves are then firmly bound with a few turns from the middle of the straw-rope, the two ends of which are fastened on opposite sides of the stack. When carefully built and thatched, a stack will completely keep out rain, and be quite secure from high winds. Materials for thatching, and straw-ropes, should always be made before harvest, so that no delay may arise from this in the event of wet weather. The thatcher stands upon a ladder, placed on the sloping roof of the stack, and lays on the straw in handfuls, from a quantity placed within his reach. One end of the straw he thrusts into the butt of a sheaf, and the other end hangs over the stack. He thus progresses upwards, making each handful overlap the other; and having drawn the top to a point, he binds the whole covering securely down with a series of tough oat-straw ropes.

Stacks are sometimes constructed in England on a timber platform raised upon stones, and over the stack the framework of a perfect barn is placed, which can be either tiled or thatched. This is said to afford greater security to the crop, and to be less expensive than annually thatching. The price of erection is said to be comparatively trifling, when the convenience of such buildings is considered; and they have been known, when well put up, to last for thirty years.

Thrashing is either performed with the flail or the thrashing-mill. The use of the latter we by all means recommend in preference on arable farms of above one hundred acres in extent. The machine may be driven by water, horse, or steam power, according to circumstances. Several improvements have been made on thrashing-mills since their first invention. The unthrashed corn is now made to pass through two revolving rollers, while it is acted on by beaters placed lengthwise upon a large cylinder or drum, which moves at the speed of 2500 feet in a minute. The great essential in thrashing is to have regularity of motion, and the grain to be equally fed into the rollers. One man should be employed to feed in the corn; one man, or two boys, to carry the sheaves; and a woman to untie and place them on a table near the feeder. Other persons are employed in raking and carrying the thrashed straw to the straw-house, where it is built. When the machine is driven by steam or water, it is generally the case that one or two winnowing-machines, according to the power employed, are attached to the thrashing-mill; and thus the expense of preparing the grain for market is considerably lessened. A powerful machine will thrash from two to three hundred bushels in nine

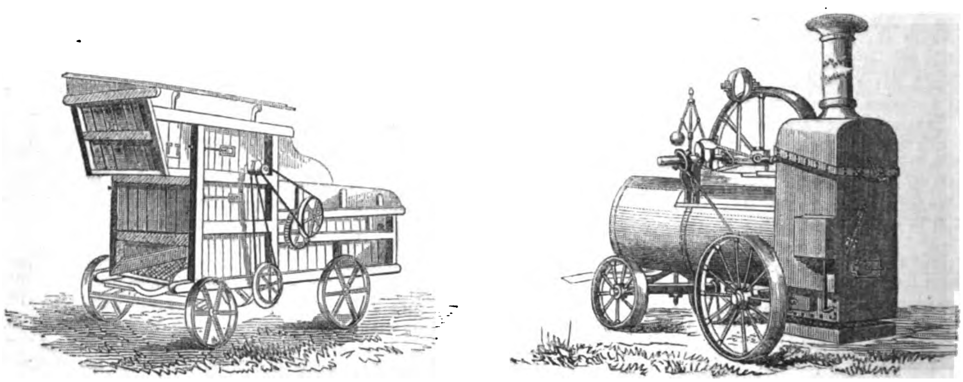

Fig. 23.—Clayton and Shuttleworth's Thrashing-machine and Portable Steam-engine.

hours; and allowing for wages and wear of machinery, the expense of thus preparing grain for the market is under one penny per bushel.

Various improvements in thrashing grain have been introduced. The well-known *peg-drum*, with or without feeding-rollers, effects a saving of power, and does not break the straw so much as the common beater, in separating the grain. The small, high-speed beating or rubbing drum, so much in use in England, has lately been introduced into Scotland; and, as its construction is better understood, it is giving greater satisfaction. On the large farms in England, portable steam-engines, though more costly than the fixed, are preferred by farmers, who have yards for feeding cattle in various parts of their holdings, for the purpose of effecting a saving in the carting out of the manure. The above cuts represent Clayton and Shuttleworth's portable engine and thrashing-machine.

Winnowing is a process performed by the aid of wind, by which the chaff of corn is separated from the grain. Winnowing-machines, or fanners, as stated before, are sometimes attached to thrashing-mills, and they are a necessary appendage to every farm, either in conjunction with the thrashing-mill, or separately. Some farmers winnow their grain by hand-fanners, which are thought to be steadier in the motion than when driven by machinery, and consequently the grain is more thoroughly cleansed. After thrashing, the grain is regularly dressed in the clean-corn room by means of fanners, riddles, and sieves; and this final dressing is regulated according to the state in which the grain comes from the thrashing-mill. By the process of winnowing, chaff, bits of straw, the seeds of weeds, and other refuse, are separated from the grain; and it is a wise precaution to boil the latter before putting them on the dunghill, which will effectually destroy their vegetative powers.

The different qualities of grain are also separated from each other, by which it is rendered more valuable than when the good and bad are mixed together. The thorough cleaning and dressing of grain are of great importance to the farmer; and he will find it to add to his profit in the end to have this effectually done.

Barley undergoes a process called *hummelling*, by which the awns are broken off from the grain. The machine is composed of a vertical spindle enclosed in a cylinder, and furnished with arms which act upon the grain. It is sometimes attached to the thrashing-mill, and sometimes driven by a separate power. The grain is put in at the top of the cylinder, and as it passes through, the awns are broken off by being struck by the arms attached to the spindle. A more simple process is, after the barley is thrashed, to take off the head of the drum, and put on another cover of tin, perforated with small holes about three-sixteenths of an inch wide. The barley is passed through the rollers, and by this the awns are rubbed off.

After being dressed and made ready for market, grain should be kept very dry, in a granary free from damp, and impervious to the incursions of vermin. It is, however, the best plan not to thrash grain till it be required for market, because it loses in weight, or shrivels in bulk, by keeping. It also loses in weight, though to a much less extent, by being kept long in ear in stacks; and therefore the sooner grain is thrashed and carried to market, the greater will be the return, supposing there be no rise in price.

ECONOMY OF ROTATIONS.

The majority of the crops which have already been noticed are cultivated to a greater or less extent on most farms; but peculiarities of soil and climate, distance from markets, besides many other circumstances, conspire to render particular crops more prominent objects in the rotation of one district than another. Indeed, the practical economy of British rotations is a most interesting subject, though one that has received comparatively little attention. Our space being necessarily limited, we shall only discuss the more important heads.

Norfolk has long been celebrated for its agriculture; and though the art has made great advances within the last century, it is curious that the rotation of crops in that county has undergone little change during so long a period. Mr Caird has fallen into the common error of attributing the founding of the Norfolk four-course rotation—turnips, barley, clover, wheat—to the late Lord Leicester; whereas the truth is, this rotation was generally practised long before his lordship became a farmer. Mr Coke only came into possession of his estate in 1776; but Arthur Young made his celebrated tour through Norfolk six years before this date, and he then gave the following account of this rotation: 'It is a noble system, which keeps the soil rich, though some farmers depending on their soils being richer than their neighbours'—for instance, all the way from Holt by Aylsham down through the Flegg Hundreds—will *steal* a crop of peas or barley after wheat; but it is bad husbandry, and has not been followed by those who have made fortunes.' In recommending a change in this system of cropping, Arthur Young shews us that *high farming* had already taken hold in Norfolk. The modern improvements that have taken place, have not been in the direction which this accurate observer anticipated. He writes: 'If I may be allowed to hazard an idea on this point, I should venture to condemn the ploughing up the clover the first year, and for these reasons: it is exhausting the land more; two crops of corn in four years exhaust much more than two in five years; hence appears to me the *modern* necessity of buying oil-cake at two guineas an acre.' This is admirably stated, and shews that, at that period, money-making farmers had adopted the shorter and intensified system which was afterwards carried out by Lord Leicester.

It is rather singular, however, that Lord Leicester, as it would appear, had been struck with Arthur Young's reasoning, and had pursued the very course he recommended; for, in 1783, Arthur Young paid a visit to Holkham, and his lordship was following the five and six course shift, or of having two or three years in grass. The objections to this system were, that it allowed the land to become foul, and three or four ploughings instead of one were necessary to bring it into a proper condition for wheat. Commenting on this practice, Young again writes: 'On our good lands we never think of giving more tillage than one ploughing, and get as fine crops as can be seen; now, the necessity of tearing a loose soil to pieces, the fault of which is too great looseness, while no such necessity exists on much stiffer soils, appears to be quite a paradox.' This extra cultivation of the grass-land, however, has always been found necessary on the lighter lands in the drier counties of England for obtaining crops of wheat, when the land has been allowed to remain for a longer period than one year in grass. Thus the Norfolk farmer is in a great measure shut up to the necessity of having two white crops in four years, and of expending large sums in the purchase of cake for feeding, and of artificial manures.

The climate of Norfolk is not so well suited to the growth of turnips as the west of England, Ireland, or Scotland, but the turnip is a more prominent crop in Norfolk than it is in any of those places. Nowhere in Scotland is it raised to the extent of one-fourth of the arable land. Turnips are an expensive crop, and in the feeding of stock, do not directly pay the farmer for raising them. They, however, are a necessary part of the system in Norfolk, even when sown to so great an extent as one-fourth of the arable land.

In the Norfolk rotation, one-half of the land is in equal parts of barley and wheat, which are both high-priced grains. The raising of these two grains can better afford a loss to be made upon the turnip-crop, than if oats had taken the place of either the one or the other. In the moister climates, which only admit of inferior grains being sown, the turnip, though easily raised, never occupies a fourth of the extent of the farm, as is the case in Norfolk. The raising of the crop for feeding cattle or sheep does not pay of itself; and hence, on farms where oats are the principal grain raised, pasturing the arable land for more than one year is the course always followed.

It is highly important to draw the distinction between the cattle crops that pay the farmer, and those that do not. Mr Mechi and Mr Caird have expressed very different opinions on the economy of feeding—opinions, indeed, quite antagonistic. The former maintains that live-stock do not pay at all, while the latter affirms that they are the most lucrative sources of profit to British farmers. The truth, however, is, that such crops as turnips, which are raised at a great expenditure of labour and manure, do not yield, on the average, a direct return equivalent to the expense of raising them. On the other hand, grasses and clovers, which grow without cultivation and manure, yield a return in the feeding of stock equivalent to the landlord's rent and tenant's profits. Looking at the expenses connected with the two crops, we have always thought that the ordinary rates which a grazier will give for a field of turnips and a field of grass, are sufficient to guide us on this question.

A large breadth of turnips can only be economically raised as part of a rotation, where, as is the case in Norfolk, barley and wheat are raised to a great extent. It is for this reason that agricultural tourists, from the days of Arthur Young, have remarked with surprise, *that this crop is never raised so extensively in those districts which have a climate particularly well suited to it, as it is in Norfolk.*

Turnips, being an ameliorating and less profitable crop, are never so extensively cultivated on rich land as upon poor. On rich land, potatoes or beans, yielding more profit, are substituted; so that even where the soil is well adapted for turnips, this crop, on high-priced land, does not usually exceed one-sixth or one-seventh of the arable land of the farm.

It would be out of place, in this short article on agriculture, to enter particularly upon this interesting subject; and we shall only contrast the Scotch and Welsh systems of rotation with the Norfolk.

In moist climates, the general system is to rely to a great extent upon grasses for renovating the fertility of the land, when it has been exhausted by crops of cereals. Though cereals, as is well known, are inferior in quality in moist climates, yet they are there raised at less expenditure for manure. This circumstance, and the less amount of labour expended in cultivation, form a certain compensation, so that arable land is fully as valuable when devoted to cereals in the west side of the island as on the east. These principles are well brought out in Mr Read's essay on the farming of South Wales, contained in the *Journal of the Royal Agricultural Society*. In answering the question, 'How far it is desirable to adopt the four-course shift in the moist climate of the west of England?' he writes:

'The only artificial manure that has been extensively tried is guano, which has been found to answer admirably for corns, root-crops, and grass; indeed, the effects are sometimes double those which are produced by the same manure in the east of England. The great activity and increased luxuriance which are imparted to all crops by the application of good fertilisers, are conspicuous to any one who has seen the small returns produced by heavy dressings given to the gravels of Norfolk. The Welsh farmer, therefore, should adapt his system of improvements to his own soil and climate, and not to that of Norfolk, or any other totally different portion of the kingdom. It is always considered abominable farming to take two white straw-crops in succession; still, with moderately high farming, on good soils in this country, that abomination may be successfully practised. Experience has proved that, on the better lands, barley, after a drawn crop of turnips, will frequently lodge. Although the following course cannot be defended on the principles upon which a rotation of crops is founded, yet it is one best suited to the good land of this district: 1, turnips; 2, wheat; 3, clover; 4, wheat; 5, barley.'

In Scotland, the necessity of having a large extent of land under turnips was not felt up to 1813, the date of Sir John Sinclair's Appendix to the General Report. Before the opening up of the London market by steam-navigation, the feeding of cattle was not much followed. In 1813, the six-course of rotation was most generally adopted on the best farms in the Lothians—that is, 1, fallow; 2, wheat; 3, clover; 4, oats; 5, beans; 6, wheat. On the lighter and fertile soils, the five-course was not uncommon: 1, fallow; 2, wheat; 3, barley; 4, grass, one or two years; 5, oats.

The modern improvement in these systems has been the substitution of turnips for the bare fallow. If this crop does not pay for all the expenses of its cultivation, it pays for a large part, and increases the supply of manure on the farm.

The Berwickshire four-course shift is not so productive of wheat or barley as the Norfolk. Even were so large a proportion of the arable land in turnips as a fourth, it is difficult to obtain a fourth of the land in wheat without curtailing the extent of barley. Wheat not generally succeeding well in Scotland after grass-crop, the rotation is often: 1, turnips; 2, wheat or barley; 3, grass, one or two years; 4, oats.

One great drawback to Scottish agriculture is, the difficulty of increasing the breadth of barley and wheat on lands where it is inconvenient or unsuitable to raise either beans or potatoes. Wheat in Norfolk cannot be taken with advantage after two or three years' grass, but oats can be so with great success in Scotland. But unless upon soils of good physical capacity, oats do not form so profitable a crop for forcing as wheat; and hence the expenditure for manures on oat and barley farms is much less in Scotland than on the wheat and barley farms of Norfolk.

It is often asserted that the climate of Scotland is unsuited to the growth of wheat, and that the inferior grains, oats and barley, can be raised with greater advantage. The practice of farmers who cultivate the best soils does not countenance such an idea. In Sir John Sinclair's Appendix to the General Report, a statement given of the produce of a Scotch acre, sown with the three kinds of grain, in Clackmannan, for fifteen years—from 1781 to 1795—shews that the wheat-crops during that period were more profitable than the other grains, which were also more subject to variation in their amount of produce. Thus: Oats varied from 49 bushels to 26; average, 42; value, £5, 9s. 4d. Barley varied from 57 bushels to 18; average, 39; value, £6, 4s. 5d. Wheat varied from 43 bushels to 25; average, 35; value, £9, 15s. 5d.

The prices were low during the whole series of years, with the exception of the last. The superiority in value of the wheat over the other two crops is considerable. The results indicate that, although it may be profitable to cultivate spring crops under an inferior system, improvements in Scottish agriculture, where the climate is suitable, must evidently take the direction of increasing the extent of the two most valuable cereals, barley and wheat; for if no potatoes are raised for export, these are the only grains which will afford the basis for higher farming, on the same principle that potato-farms require more capital or can be higher farmed than where cereals only are raised. But the other aspects of this question will be best treated in the paper on CATTLE AND DAIRY HUSBANDRY.

FARM-BUILDINGS.

Each farm must possess a residence for the farmer, cottages for the servants, and buildings for the stock and crop. The *farm-house* should be commodious and plain, with an extent of accommodation about equal to that which those have who are engaged in commercial pursuits in town, employing the same amount of capital. The cottages for the servants should also be plain and roomy, and internal convenience should be more studied than outward ornament.

Proper offices are essential to the economical disposing of the produce of the farm. The corn crops are usually thrashed there, and a large portion of the green crops is consumed by stock, which must be well provided with shelter from the cold. When few turnips were raised, and few cattle fed, large open courts were best suited for converting the straw into manure. Now, however, in many cases, the excrements of the stock are sufficient for wetting all the straw, and hence has arisen the practice of box-feeding. In this case, the solid and liquid excrements are carted out along with the straw, which acts the part of a sponge. This is, no doubt, an excellent way of manufacturing home-made manure. It takes a considerable quantity of straw, however; and as more green crops are raised and consumed on the farm, sufficient straw cannot be got to absorb all the liquid; hence a saving of the straw is effected by stall-feeding, when the excess of liquid must be collected into tanks, and otherwise disposed of. When it is remembered that ammonia cannot be purchased in the market at the present time under £60 per ton, the utility of husbanding this material when it is freed as the excrements of the stock decompose, must be self-evident. If the solid excrements are kept in a compressed state, no fermentation takes place; and if the manure is of good quality, it should be applied to the fields at once. Liquid manures should be carted out,

or distributed by pipes, when the plants are in a growing state, otherwise part of it will be washed out of the soil. Covered farm-yards are rapidly extending over the country. It is the cheapest and best way of erecting farm-offices. Our frontispiece represents a bird's-eye view of a 'Model Farm-steading,' designed by Mr J. Lockhart Morton, for a farm of 500 acres, and a model of which was commended by the judges of the Berwick cattle-show in 1854.

The steading is on the covered principle, all the various departments being under one roof. It will be seen by the ground-plan on page 518, that the food-preparing houses are ranged as convenient as possible to those in which the food is to be consumed, and that the relative positions of every other department have been carefully studied. This is the great point to be attended to in the formation of all homesteads, whether open or covered.

Ventilation.—'Without good ventilation,' to use Mr Morton's own words, 'a covered homestead must be a nuisance. All the apartments are so arranged that, unless fresh air circulate through them, and they are kept perfectly clean, there must constantly be unwholesome effluvia in the interior—the foulness of one apartment being communicated to another. The system of ventilating this model farmstead is certain to give most satisfactory results, if only ordinary care be taken to keep the different houses as clean as they ought to be.' His arrangements are briefly as follows:

Under each feeding-passage is built a circular ventiduct or air-shaft, thirty inches in diameter; in connection with these there are feeding-mouths with gratings on the outside of the building; inside, there are numerous finely perforated gratings; by sliding-valves, wrought by a cord and pulley, the supply of air is regulated. Besides these, there are gratings every ten or twelve feet along the exterior walls, perforated so as to admit near the floor a considerable quantity of air. The roof, too, is provided with ventilators with vertical spars, and openings are left here and there in the sarking to act as induction and eduction tubes. The numerous perforated apertures throughout the building will admit twice the quantity of air required for the respiration of the animals, and are so under command that they will neither admit flies in summer, nor too large a supply of cold air in winter. A covered steading, somewhat similar in construction to Mr Morton's, has been erected at Glen, in Peeblesshire, where the ventilation of the enclosed cattle-courts, &c., is admirable.

We would only remark, that to carry out this principle of ventilation is somewhat expensive. A cheap and yet efficient system of ventilation for cattle, is to cover the yards with pan-tiles without plaster or lath. Those who wish to see farm-offices economically erected, at the same time combined with the most perfect ventilation, we would recommend to visit some that have been lately built on the property of Lord Kinnaird, Rossie Priory, Perthshire. As a general rule, farm-steadings are erected at too great an expense.

Choice of a Farm.

Farms, as to size, are usually divided into small farms under 100 acres; moderate-sized farms from 100 to 250 acres; and large farms of from 250 to 1000 acres and upwards, of land fit for cultivation. Each of these sizes is adapted to particular districts and other circumstances—especially to the degree of fertility and the amount of capital employed. It is a common but injurious mistake to suppose that the more land a farmer holds, the greater must be his profits. The profit does not arise from the land itself, but from the manner of using it; the best soil may be made unproductive by bad management, and the worst may be rendered profitable by an opposite course.

In Ayrshire, where dairy husbandry is well understood, and has arrived at greater perfection than in any other part of Scotland, the farms are of moderate size, being in general from 60 to 160 English acres. A farm of about 127 acres is reckoned a good size, and on this from ten to twelve cows are kept. Sir John Sinclair recommends that a clay-land farm should not exceed 380 English acres; and he justly remarks, 'that those who grasp at having farms of a greater extent, where servants are not immediately under the master's eye, lose rather than gain by extending their land. Where the soil is of a light description, a larger extent is necessary, as in such soils sheep and cattle are frequently fed in large numbers; and a farm of this description, of from 600 to 1000 Scotch acres, or 762 to 1270 English, is not considered too large. Where farms are almost entirely employed in pasturage, or in the breeding of sheep or cattle, as is usually the case in hilly districts, there can be no precise limits to their extent; some in the Highlands of Scotland, devoted to sheep-pasture, reach 25,000 English acres.'

The selection of a farm requires the whole ability and experience of the farmer. He must attend to all the advantages and disadvantages regarding it, so that he may fully make up his mind as to the amount of rent he considers it worth, taking care neither to be too cautious nor too rash. There is one common but very erroneous rule which guides the choice of a farm—namely, the success of the outgoing tenant. If he has made money in it, or is leaving it for a larger one, numbers will flock after it, and offer a high rent, without even inspecting it. But if the tenant be unsuccessful, all his misfortunes are attributed to the badness of the land, not to his own mismanagement; and few will be found willing to take the farm even at a reduced rent. These notions are very absurd; for the management of various farmers is so essentially different, that success or misfortune may be said to depend more on that than on either rent or quality of land.

The last advice which may be offered in reference to selecting and also managing land, is not heedlessly to carry prepossessions of what is right in one country to another country in which he may chance to settle. Every country, and indeed almost every district of a country, has its own peculiar fashions in agriculture as in everything else, and the meaning of these should always be carefully studied before pronouncing on their error or inutility.

Leases and Rents.

A farm is seldom conducted properly for the legitimate advantage of either landlord or tenant, except a lease of considerable duration be granted; for if the tenant be at all times liable to be dispossessed at the mere will of the proprietor, he can have no interest in improving the land, and therefore cannot afford to pay a sum suitable to the actual capabilities of the soil. According to the modern practice of agriculture, the profits of a farm are frequently prospective; a number of years must sometimes elapse before the ground repays the farmer for his sunk capital, and his trouble in effecting improvements. The duration of a lease consequently depends on the nature and condition of the soil, as well as some other minor circumstances. It is understood that a long lease is a much greater stimulus to spirited farming than a low rent. If the lease be long, and the rent high, great exertion is used by the farmer; but if the lease be long, and the rent low, a slovenly mode of farming, such as is found under the 'life-leases' of Ireland, may in general be expected. It appears, from all experience in Scotland, that a lease should neither be too long nor too short, but of a moderate duration, as nineteen or twenty years.

The connection between landlord and tenant is that of a disjunctive copartnery. The tenant trades upon a certain sunk capital of the landlord. The question, then, as to what is to be paid in the form of rent, is

[Continued on page 520.]

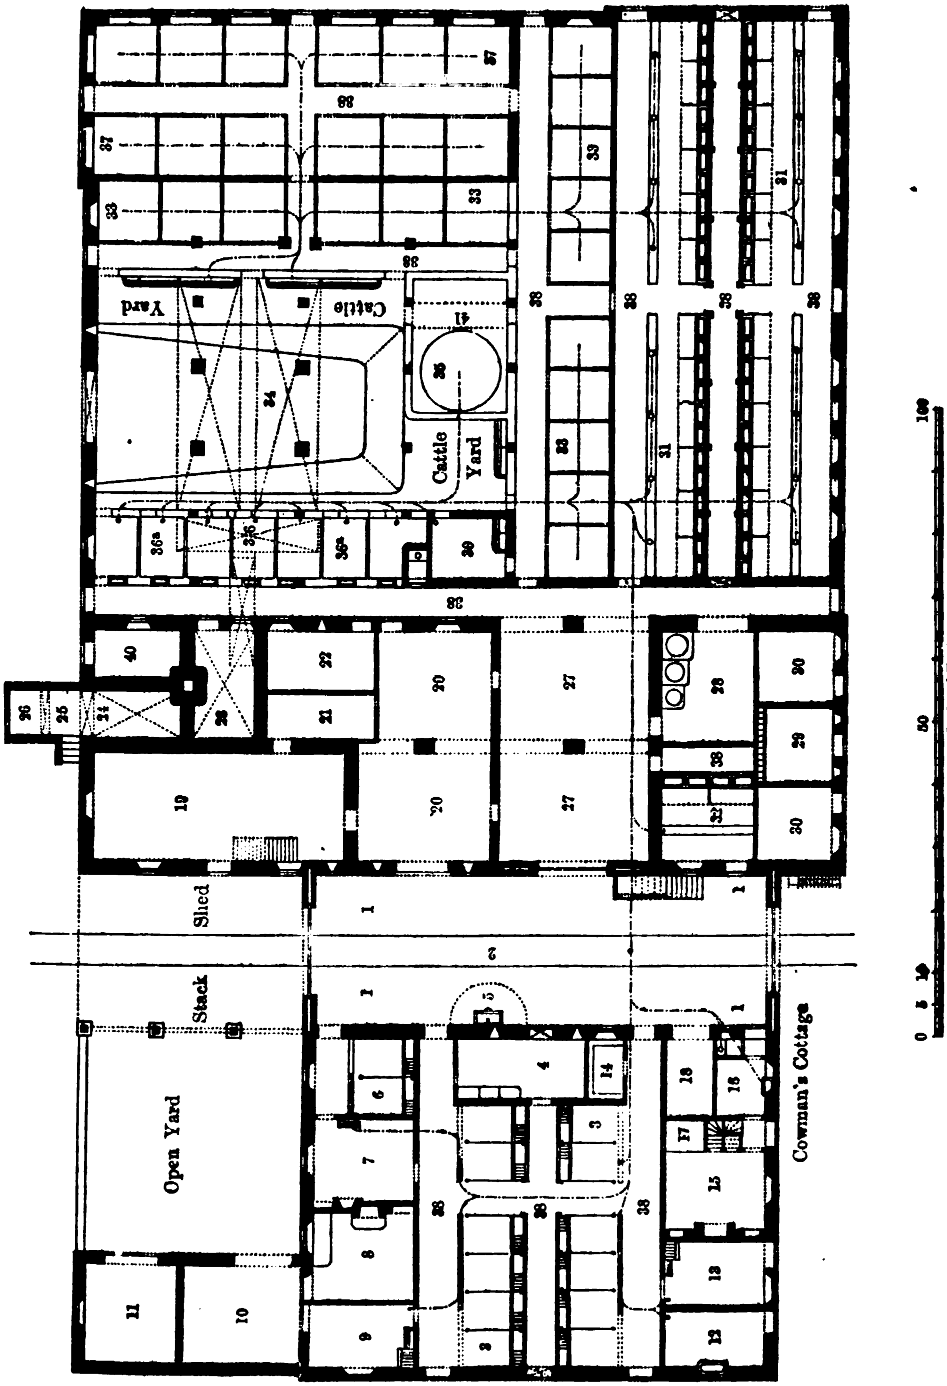

Fig. 24.—GROUND-PLAN OF MORTON'S MODEL COVERED FARM-STEADING.

1 is a covered yard or roofed court, extending from the front to the back of the building, including a stack-shed; and by means of a railway (2) running the entire length, and from one side of the farm to the other, the heavier cartages may be performed. For instance, stacks of grain, built on four-wheeled frames on the outskirts of the farm, may be conveyed at any time to the homestead, without being broken into cart-loads; and as the stack-house is alongside the thrashing-barn, the sheaves may be pitched at once from the rick to the feeding-board of the thrashing-machine. This covered court may also be used for storing temporarily unloaded grain, hay, &c.; and even should there be a scarcity of accommodation for fattening stock, a series of movable cattle-boxes may be placed in the centre division, and with the sliding-doors at both ends partially closed, the animals would be comfortably housed. It is intended, also, that this court should serve as a cart-shed, the carts being placed at the sides. At a height of ten feet, a projecting platform runs along each side, four feet wide, and railed in front, communicating between the various lofts and granaries, and for providing a suitable store-place for the lighter implements and tools not in constant use. A light drawbridge joins these platforms, over which cut straw or bruised grain may be conveyed from the barn-lofts to the horses' bins, and supplied through spouts in the floor above. The roof of this court is an iron girdered one, with a quantity of rough plate-glass in it.

3 is the work-horse stables, which may be entered either by the west side or by the covered court. Instead of facing a dead-wall, the animals stand in the reverse direction, and are fed through sliding sparred doors from the feeding-passage in front; this renders it more cheerful, and insures better ventilation, besides making the process of feeding more speedy. 4 is the hay-house; and in one corner are placed the corn-chests. 5 is a semicircular trough containing water for washing the horses' feet: it may be turned on when required, and deepens gradually to fifteen inches; and the waste water and dirt may be run off by a plug at the bottom. 6 is the riding-horse stable, fitted up in the same manner as that of the work-horses; 7, the harness-room, with the ploughmen's sleeping apartment overhead; and 8, the carpenter's shop; 9 is a loose box; 10, the implement-house; 11, for portable manures; 12, the bull's house; 13, the mare and foal's house; and 14, a dispensary, being all exceedingly useful departments, and scarcely to be dispensed with in a steading of this kind. 8 may be used simply for the lighter kinds of carpenter's or smith's work; but by fitting up, might be made into a regular workshop. The cowman's or grieve's cottage is so arranged that its occupant can get access to any part of the steading without having to go into the open air. Besides a living room, 15, scullery, 16, and bed, 17, on the ground-floor, two sleeping-apartments are provided above. Contiguous to this is the gig-house, 18.

19 represents the dressing-barn — the thrashing-barn and thrashing-machine being immediately above. As the straw leaves the machine, it is carried into the adjoining straw-house, 20, by an endless web. In connection with the thrashing-loft, is a sack-store with a lock and key, the whole enclosed with sparred wood-work. At the back of the barn, and connected with the thrashing-loft, is the chaff-house, 21, which may be entered from the straw-barn when the contents are required. Alongside this is the oil-cake bruising-house, 22, with necessary power from the engine-room behind. The engine-house, 23, though partly floored by the granary, is arched with brick, to prevent the risk of fire; and proper means are taken to carry off waste steam and obtain fresh air. The boiler, 24, is fired from the outside—a corrugated iron roof projecting over the firing-pit, 25, to protect the fireman in inclement weather; and beyond is an arched-over fuel-depôt, 26. Under the engine-house, a narrow arched vault, arranged at the end of the liquid tanks, is provided; and either here or in a corner of the engine-house, the liquid-manure force-pumps will be placed. 27 is the forage-house—a receptacle for turnips or any other food to be given to the cattle; and it and the straw-house are placed as nearly as possible in the centre of the homestead. Loaded carts can enter from the covered yard; and immediately adjoining is the boiling or steaming house, 28, where soft meat is prepared. The forage-house is lighted by borrowed lights from both ends, and by means of two strong plates of rough glass in the floor of the store-loft above. The granaries extend above the forage-house, half of the straw-barn, the chaff-house, and all the way to the gable at the engine-boiler. Part of this range may be set apart as an oil-cake store, and another portion as a site for the grain-bruisers. A stair in the covered yard gives easy access to the granaries on the one end, and at the other they communicate with the thrashing-barn by a side-door. 29 is intended for *web*-footed poultry; 30 are two infirmaries for sick animals, the doors of which open from the outside, so as more completely to isolate them from the cattle-houses; and above those are placed a poultry-room and dove-cot. It may be well to add, that the poultry-rooms can be heated by pipes from the boiling-house behind. On the west side of 30 is the hen trap-ladder. 31 represents the stalled-cattle houses; sliding sparred gates are fitted up, at which they are fed, and which insures better ventilation than if solid boarding were employed. The divisions should consist either of cast iron or flag-stone, or they may be formed of well-seasoned wood, impregnated with Boucherie's preservative material, or Bethell's creosote. 32, the dairy-byre, or cow-house, is fitted up in the same principle as the feeding-byre. Nos. 33 are intended to represent cattle-boxes; these are sunk nearly three feet below the level of the passages, to be gradually filled up as the manure is made; before each stall there is a gate from the passage, and the manure can be conveyed away by means of a barrow. It has been found upon farms where there is much straw to be converted into manure, that the system of feeding cattle in boxes with sunk floors has been attended by good results; there is, besides, less likelihood of bad odours arising. The cattle and manure yard, 34, is not meant to be a wet, irregularly spread dung-heap, which is to fill the whole steading with an unbearable stench; it is intended to serve as a large cattle-box, whereon is deposited the manure from the stalled house and stable, and all that is not washed into the tanks: this being bedded over with straw, and trodden down by the animals, will always be kept solid, and effluvia by that means avoided. But if there be not a good supply of straw, we would by no means commend the adoption of this department of a covered homestead. This yard is excavated to the depth of six feet, and slopes from the gateway towards the inner end. From the passage in front of the feeding-boxes, the animals in this court are fed, as merely a low stone-wall surrounds it. Under this court, as shewn by the dotted lines, lie the liquid-manure tanks. If the system of dissolving manure be practised, 35 shews where a pit may be sunk, the top of which should be covered with an iron grid. After the solid manure has been washed through the grid by water, the refuse is raked off into the dung-yard; and by means of a handle which opens a valve at the bottom of the pit, the mixture flows to the tanks; but if this system is to be dispensed with, a simple well will be sufficient to hold the drainings from the dung-heap and cattle-stalls. No. 36 shews where the gearing-pits range; this gearing, in connection with the engine, works the agitators in the liquid tanks, and space is left for a force-pump. Above this range, 36ᵃ, are placed the piggeries, each house provided with a swinging-door, at which to supply the food. Nos. 37 represent space for the accommodation of a hundred sheep, on sparred floors. The outside walls of this house may be of open brick-work, with slide-boards inside. The different pens are enclosed by light wood-work, with gates opening from the feeding-passage. Nos. 38 shew the leading passages of the steading: 39 is the calf-house, and 40 the tool-house.

determined by the value of this capital, and what return it will produce annually on an average of years. From this return the tenant is supposed to draw one share, while the other is handed to the proprietor of the ground. With respect to grazing-farms, they are let on the principle of how much stock they can regularly maintain; and not being liable to the same expenses for management, both landlord and tenant receive larger shares out of the gross product. In some instances, proprietors, from negligence or a wish to retain an undue power over their tenants, delay the renewal of the farmer's lease till the period is almost expired. This is highly injurious to both parties; as, while uncertain if he is to continue on the land, the tenant will naturally be slack in his exertions to improve it, or even to maintain it in a fair condition. This evil might be easily avoided, by the proprietor renewing the lease of his tenant a few years before the expiration of the time. When a landlord has an intelligent and industrious tenantry, with capital sufficient to cultivate their farms to advantage, he ought to be cautious of parting with them. Should the land have materially increased in value during the lease about to expire, it will be found most advantageous for the landlord to nominate a judicious valuator, and to offer the farm at the declared rental to the existing tenant, without bringing it to public competition.

In drawing up leases, it is customary to introduce clauses restricting the tenant to certain rotations of crops, manuring, &c., applicable to the few years which precede the termination of the contract. These clauses, and also others respecting the keeping of fences and roads in repair, are sufficient in all ordinary cases. Some landlords may be desirous of prescribing the exact mode of management of their farms; but this has a discouraging and injurious effect, and should therefore be avoided, except in what may be called improving leases, or engagements to improve the land in a certain manner. With regard to the form of a lease, it should commence, says Sir John Sinclair, 'with the necessary preamble, stating the parties contracting, the situation of the property to be leased, the extent of the farm—a plan of which ought to be subscribed by the contracting parties—the duration of the lease, and the time of entry: it is then proper to enumerate, 1*st*, The powers and privileges reserved to the landlord; 2*d*, The obligations incumbent on the tenant; and 3*d*, The stipulations obligatory upon both. Leases thus drawn up would not be liable to much uncertainty or dispute; and lest any should occur, it is expedient that a mutual obligation for settling by arbiters should be inserted.'

In modern farming, rent is altogether payable in money, or partly in money and partly in grain. The system of grain-rents is yearly extending in Scotland, and is highly popular with the tenants, as it equalises in a great measure the risk of bad seasons and low prices between farmer and landlord—not requiring from the former a fixed amount of rental from an uncertain and fluctuating source. Thus, for example, a farm at the nominal rental of £500 a year would be let for £250 or £300 in money, the remainder being payable in so many quarters of wheat, barley, and oats, at the fiars' prices* of the county. When the rental is estimated at so many quarters of these grains, the average of the three is taken, under the title of the *Triple Quarter;* but frequently wheat alone is taken as the convertible grain, and then, as the case may be, nine or ten bushels are given per acre. In order still more to equalise the fluctuations in price—that is, to prevent the rents from rising too high in scarce years, and falling too low in plentiful harvests—it is becoming usual to fix a maximum and minimum price, at which the grain shall be convertible into money when the fiars' prices exceed or fall below them. Thus, if the maximum for wheat be fixed at £3, 16s., and the minimum at £2, 10s., it will prevent a ten-bushel rent from falling below £3, 2s. 6d., or rising above £4, 7s. 6d. per acre.

The periods of the year, at which tenants remove from and enter farms, are very various. In many parts of England, Michaelmas, or 29th of September, is the period for both grazing and arable farms, that being the most suitable on account of the number of great stock-fairs held at that time, and other circumstances. In Scotland, Martinmas, or 11th of November, is the usual period. It is considered to be a most advantageous rule, that in all cases the removal of an outgoing tenant should be entire, not partial, as bit-by-bit removals too often lead to disputes between the retiring and entering individuals.

Arrangement and Management.

With respect to the arrangement and management of a farm, we cannot do better than extract the excellent digest of rules from the *Code of Agriculture:*

'1. The farmer ought to rise early, and see that others do so. In the winter-season, breakfast should be taken by candle-light, for by this means an hour is gained, which many farmers indolently lose, though six hours so lost are nearly equal to the working-part of a winter-day. This is a material object where a number of servants are employed. It is also particularly necessary for farmers to insist on the punctual performance of their orders.

'2. The whole farm should be regularly inspected, and not only every field examined, but every beast seen at least once a day, either by the occupier himself or by some intelligent servant.

'3. In a considerable farm, it is of the utmost consequence to have servants specially appropriated for each of the most important departments of labour; for there is often a great loss of time where persons are frequently changing their employments.

'4. To arrange the operation of ploughing, according to the soils cultivated, is an object of essential importance. On many farms there are fields which are soon rendered unfit to be ploughed, either by much rain or severe drought. In such cases, the prudent farmer, before the wet season commences, should plough such land as is in the greatest danger of being injured by too much wet; and before the dry period of the year sets in, he should till such land as is in the greatest danger of being rendered unfit for ploughing by too much drought. The season between seed-time and winter may be well occupied in ploughing heavy soils, intended to be laid down with beans, oats, barley, and other spring-crops, by means of the scarifier. On farms where these rules are attended to, there is always some land in a proper condition to be ploughed.

'5. Every means should be thought of to diminish labour, or to increase its power. For instance, by proper arrangement, five horses may perform as much labour as six, according to the usual mode of employing them. One horse may be employed in carting turnips during winter, or in other necessary farm-work at other seasons, without the necessity of reducing the number of ploughs. When driving dung from the farm-yard, three carts may be used—one always filling in the yard, another going to the field, and a third returning. By extending the same management to other farm-operations, a considerable saving of labour may be effected.'

To this digest it may be added, that the farmer should habituate himself to keep regular accounts of his affairs, which may be done by means of a cash-book for all outlays and receipts as they take place; a labour-book, in which to mark the commencement and time of work of every individual employed; a journal for

* Fiars' prices in Scotland are the average prices for each county, as fixed by the sheriff with a jury, upon the evidence of the principal buyers of grain within the district. The average is usually struck about the beginning of March for the crop of the preceding year.

entering daily transactions and memorandums; and a ledger, in which a special debtor-and-creditor account is kept of every department, as well as a general account of the whole concern.

WASTE LANDS.

According to the agricultural statistics which we now possess of Scotland and Ireland, and of one-fifth of England and Wales, taken in eleven sample counties, it appears that out of the 74,000,000 acres in the United Kingdom, only 42,000,000 are in cultivated arable and pasture, the remaining 32,000,000 being thus distributed:

	Acres.
Woods and plantations, ...	2,000,000
Sheep-walk (Scotland), ...	7,000,000
Unenclosed pasture (Ireland), . . .	8,000,000
Mountain, peat, and flat red bog (Ireland),	3,000,000
Other waste—say, ...	12,000,000

Much of this large proportion of our territory is either situated at such an altitude, or else so naturally barren, as to be hopelessly beyond the reach of improvement; but estimating from Mr Couling's valuation in the year 1827, and the amount of land enclosed since that time, we have now about 16,000,000 acres capable of being added to the arable and pasture of the kingdom.

Considerable misapprehension exists as to the character and capabilities of these cultivable waste lands, and we have no reliable authority furnishing us with exact information; however, there is sufficient evidence to shew that they generally consist of the naturally poorest or most unfavourably situated ground, or such as is least remunerative to the husbandman, owing to the heavy outlay required for its reclamation.

From the great decrease of enclosures, during the present century, in spite of the vast and rapidly accelerating increase of population and demand for food, it is plain that but little ground yet remains waste which it would be worth while to cultivate, under our present system of tenancy and our present order of agriculture; unless, indeed, it can be shewn that there exist any wild tracts of rich soil, that are locked out of reach of the free investment of capital and industry, only by some defective legislation, some anti-social privilege, or unrighteous ownership. Here and there, it is true, are patches of land upon which legal or personal considerations forbid the eager cultivator to enter; such, for instance, as Pill Moor, in the North Riding of Yorkshire; and again, Cannock-chase, in Staffordshire, the property of the Marquis of Anglesea—14,000 acres in a populous district, and one-half capable of profitable cultivation, being chiefly dry turnip-land on red sandstone. And in the Scotch Highlands, we hear much of honest industry in sheep-farming being interdicted on a large scale, for the mere sake of creating sport for the deer-stalker. But nowhere do we find tracts of dense weald and tangled copse, such as once overspread the fertile clays we are now draining and grain-cropping; in few places are there districts of wild heath and wold precisely such as have been converted into turnip and barley farms; and still more rarely are there wide fens and marshlands lying unembanked and unreclaimed. There are parks which might be brought into tillage, forests that might be cleared, sandy wastes that might be planted, bogs which might be drained, sheep-walks capable of improvement, and salt-marshes needing enclosure from the ocean; but all, generally speaking, at an expense which renders the propriety of the attempt somewhat questionable. The notion, then, that there exist wide-spread tracts of good land, unprofitably waiting till their owners permit them to be tilled, is not correct; there are but few plots capable of ordinary culture which are not already brought under the plough, or appropriated to the pasturage of cattle. British agriculture has arrived at that point of its history in which the problem is, how to increase the yield from each acre, rather than where to extend the area operated upon. And when we remember that, of the 23,000,000 acres of wet land cultivated, or capable of cultivation in Great Britain, less than 2,000,000 only are permanently drained; when we consider how far behind the two or three best counties is the agricultural management of the rest of the kingdom; and how small a proportion of the estates, even in the first-class localities, are farmed in the highest manner, we can easily see that, by a simple extension of the best husbandry, and the application of more capital and intelligence over the surface already in cultivation, the produce of the United Kingdom might be doubled, or, at anyrate, prodigiously augmented, without our having recourse to the costly reclamation of waste lands. Still, so long as the system under which land is occupied continues to trammel enterprise and improvement, and so long as science and practical skill are so partially diffused among farmers, the waste lands will be resorted to by bold proprietors and venturesome tenants; and that instinctive preference felt by the great majority of men for agricultural before all other pursuits, will not fail to lead strong-armed labourers and town-wearied mechanics to push stone-walled enclosures up the steep sides of moors and fells, to creep with gardens and green crops up the sandy heaths, to tap dropsical mosses, and bale out the tide from fat marshes.

The question as to the propriety of reclaiming a really improvable waste is, in any particular case, to be satisfactorily answered by ascertaining at what expense, in relation to the probable profit, the process may be performed. A barren rocky desert may be rendered productive by covering it with soil and manures brought from a distance of miles, aided by years of skilful tillage; but will the returns in produce be an equivalent for the excessive outlay? Gold itself may be purchased at too high a price, and so may agricultural improvements. In all projected undertakings of land-reclamation, whether by capitalists or by those who propose to expend only time and personal labour, it is necessary to calculate what will be the probable return, within a moderate length of time, for the outlay—always keeping in view the prospective prices of produce during the period.

We will now proceed to describe the nature of the various waste lands, the best means to be adopted in reclaiming them, and the results which may be expected to reward the enterprising improver.

MOORLANDS, HEATHS, DOWNS, AND HILLY WASTES.

Our principal English *moors*, as distinguished from the fells and actual mountains, are in the counties of Northumberland, Durham, Cumberland, Lancaster, York, Stafford, Chester, Derby, Devon, Cornwall, Somerset, &c.

The Yorkshire moors are the most extensive and important in England. The eastern portion, principally in the North Riding, rise about 1000 feet above the sea. The surface of some of the hills is entirely covered with large freestones; and in other places mosses, sometimes very large; the prevailing soil being peat-earth, which is generally covered with heath. On that portion called Hambleton Hills, the soil is much better, being good loam on a limestone rock. The climate is dry, but cold and backward; however, portions of these lofty and exposed regions have been brought into tillage; and sheep are being fed on what used to be the haunt of the wild mouse and the mole, and luxuriant oats wave before the wind that used to whistle through the whins and the heather.

The western moorlands, almost equally divided between the North and West Ridings, are of very great extent, but not generally so sterile as the eastern. Many

of the hills are covered with fine sweet grass; while in other places there are large tracts of heather mingled with grass, bent, or rushes. On these waste lands of the millstone-grit formation, the productiveness of many enclosures shews what a large extent yet unreclaimed is capable of. There are many instances of this high ground growing nothing but heather, and not realising more than about 1s. 6d. per acre, shooting included; whilst immediately adjoining, on the same level, are cultivated plots letting for 20s., 25s., and up to 30s. per acre, and producing excellent crops. There being no very great proportion of peat on these lands, their reclamation would be the sooner accomplished.

The Derbyshire Peak is very wild and barren, not so much from its altitude as from the steep, rugged, and nearly soilless sides and crags of the limestone and the millstone grit, and from its bogs and moorlands covered with heath and boulder-stones of every size; while the streams carry down the waste of crumbling grits and shales in their peaty, brackish waters, to enrich the meadows and vales below. The soils on the grit are chiefly of a sandy kind; the great difficulty in cultivating being the first clearance or removal of the rocks and blocks everywhere scattered over the surface. Vast tracts have been cleared and taken in; and Mr Rowley gives, in the *Royal Agricultural Society's Journal*, the following account of the method of encroaching upon the moor: 'Stanton House, the farm of W. P. Thornhill, Esq., is 715 feet above the sea-level. A great part of the estate has lately been taken from the waste at an average cost of £15 per acre, one portion having cost £50 an acre in stubbing, ridding, and blowing up grit-rock. The first process was the draining at eighteen or twenty inches deep, six and seven yards apart. This was found insufficient; and deeper drains, from three to four feet, put in, and a perfect though expensive drainage completed. The rotation of cropping followed is the four-course: the turnips are grown with bones and guano, and a heavy dressing of farm-yard manure; and the bulk of them are consumed on the land by Leicester and Shropshire-down sheep. The average produce of oats is seven quarters, and of wheat, four and a half quarters, per acre, of excellent quality. Favoured by a southern aspect, and sheltered from the north and westerly winds by extensive plantations of larch and spruce, the farming at this elevation is under advantageous circumstances, and very different to that on the opposite hills facing the north and east. At this elevation, in no part of the midland counties has autumn-wheat been successfully grown; while in the mountains, wheat is never attempted at elevations from 100 to 200 feet lower.'

Cornwall contains about 200,000 acres of waste, the greater part being held in common by surrounding farmers. To shew what skill, enterprise, and capital will do on some of the most exposed parts of the granite wastes, Mr Karkeek says, in the *Royal Agricultural Society's Journal:* 'Let the reader imagine a piece of waste strewed over with granite blocks, some of immense size, with heath and furze shooting up in the interstices, at an elevation of 600 feet above the sea-level; and notwithstanding these natural obstacles, I witnessed a short time since, on an estate of only 150 acres—not many years since reclaimed from the Sancreed wastes—130 head of cattle, Devons and short-horns, 100 pigs, and 35 horses and colts. The average produce is from 45 to 60 bushels of oats, from 18 to 21 of wheat—not much grown—300 bushels of potatoes, and from 18 to 25 tons of turnips. It frequently happens that the first crop of potatoes raised on this reclaimed land will more than repay the expenses.' And again: 'The Messrs S. & R. Davey, of Redruth, have broken up about 100 acres of thin rocky soil on the slate-formation, at a cost of enclosing and cultivating—including the expense of the first crop—varying from £10 to £11 per acre. At the commencement of their undertaking, the land was manured with bone-dust and lime for wheat; but the produce was only fit for pigs and poultry. The present method of cropping is Swedes or turnips eaten off, followed by oats and grass and clover seeds. The crops will average from 60 to 70 bushels of oats, and from 18 to 25 tons of Swedes per acre. This has been effected entirely by the use of bones and guano. It has been correctly ascertained, that in the parishes of Perranzabuloe and St Agnes, there are 7037 acres of the same kind of waste, 5000 of which would pay handsomely for reclaiming.'

In North Wales, there exist extensive tracts of waste upon the mountain-sides capable of cultivation. On the Hiraethog range, the luxuriant growth of the heath, fern, and foxglove in many places, is a clear indication of the riches that are in store for the first adventurer who may attempt to break up the almost desert waste; and many patches of deep hazel loam are seen, which have been lately reclaimed from the wild state, now covered with oats and grass of the best description. There are wide-spread tracts of land in Merioneth and Montgomery-shires, which, by paring and burning, draining and liming, would produce excellent crops of turnips and rape—enabling the farmer to maintain as large a flock of sheep in winter as in summer, instead of being compelled to draft them off to lowland graziers, as at present. Before such heath or bog land can be profitably cultivated, it is indispensable to apply lime; and the question, therefore, of future improvement is in a great measure dependent upon the facility with which this substance is procurable.

We may here speak of the processes of Burning and of Liming.

Paring and Burning.—Suppose the plot to be reclaimed has been surrounded by a substantial stone-wall or other fence, dried by stone or tile drains if necessary, and all stones that are visible upon the land grubbed up and carted or conveyed off upon sledges. The paring is to be done, if possible, in the months of April and May, in order to have the most favourable part of the year for drying the parings well before burning. Several paring-ploughs are manufactured; but the best method is to employ the *breast-plough* or *paring-spade*, the surface being so irregular, and very thin slices being required. The parings should be burnt directly they are sufficiently dry, as, after lying a month or six weeks, they begin to unite with the ground, and imbibe moisture from the young grass vegetating beneath them. Sometimes they can be burnt as they lie, without being collected into heaps; and in this way, the fire, in consuming the lingy side, which is undermost, chars the surface of the soil at the same time. If burnt in heaps, these should be very small, in order to secure a good black ash instead of the hard lumps of red ash produced by large fires. The art in burning is to keep a smouldering fire, never smothering it with too much earth, and keeping the outside layer of sods so close as to prevent the fire from kindling into flame. The ashes should be spread, care being taken to clear the bottoms of the heaps well out, so that the first crop may be free from patches. The cost of thus paring, burning, and spreading is about £1 per acre. The ashes require to be well ploughed in.

Liming.—When the land has been well ploughed and reduced by harrowing, the lime, having been laid for some time in large heaps, and properly slaked or brought into a powdery state, should be placed in small heaps—say one to every square perch—then carefully spread over the surface, and well harrowed in. The quantity may vary from 100 to 200 or 250 bushels per acre, according to the nature of the soil. Strong soils, of a sour or rushy nature, containing much fibrous and inert vegetable substance, require more than those of a lighter description. Lime is invaluable as a first dressing in reclaiming heath-land. It acts as a powerful stimulant upon inert fertile ingredients in the soil,

and decomposes and corrects the crude and acrid matter arising from the decay of organic bodies in virgin soils. It is able totally to eradicate the heather, alter the texture of the land, and produce a rich and sweet herbage. In the application of lime in reclaiming moorlands, it is a rule always to give abundance, and in a newly slaked condition, in order that it may have its full effect. If slaked a considerable length of time before it is applied, it does not act so powerfully either in reducing the natural herbage or neutralising the acids, as when used in a hot powdery state.

Not only for tillage, but also for improving the pasturage of the waste lands when laid on as a top-dressing—that is, thinly powdered over the surface—lime is found to have very extraordinary effects; and it is satisfactorily proved by experience that the proprietors of waste moorlands within reach of lime have only themselves to blame for their grounds continuing in sterility. Were proper arrangements entered into between the landlords and the tenants, a great proportion of the high pastoral grounds now lying in a profitless condition, might be progressively improved by simply draining where needful, and top-dressing with lime.

Devonshire comprises about 455,000 acres of waste land, much of which may be rendered productive. Dartmoor—no less than 250,000 acres uncultivated—has principally a peaty soil, which during the summer months is dry and firm; in other parts, as in Dartmoor Forest (80,000 acres), there exists a perfect swamp even in summer. The mean elevation of the district is nearly 1800 feet above the level of the sea; the climate cold throughout the greater part of the year, and materially impeding vegetation. Undoubtedly, the main cause of this unfavourable climate is the want of drainage; and it is nearly useless for private individuals to attempt isolated enclosures until all the district has been drained by a simultaneous and united undertaking.

The enclosure of Exmoor Forest, in Somersetshire—20,000 acres, at an altitude of 1000 to 1200 feet—is one of the most striking examples of the improvement of waste land. The surface is in the form of an undulating table-land, furrowed by deep stream-valleys, and covered over almost its whole extent with a moist pasture. There is considerable depth of soil on the boggy portions, which, when drained and limed, make good land; some of the peaty lands rest on a crust or pan, which must be broken through by subsoiling; while other parts have a dry soil, needing only to be pared, burnt, and limed, in order to bear fine root-crops. Rain and mists, and Atlantic gales, are the principal opponents of the cultivator; but plantations and good hedges are rising to afford the requisite shelter. The best fence for this purpose consists of a bank of earth, supported on both sides by stone-walling, five or six feet high, and six feet thick at bottom; and on the top of this, beech-trees are planted, and found to grow well. Mr Knight, the proprietor, has erected a large number of farmhouses and cottages, and constructed nearly 30 miles of road, and 150 miles of wall or bank-fencing; and a large portion having been pared, and burned, and limed, is now growing roots and grass, and indeed oats also with great success. One of the most remarkable features of the Exmoor improvements consists in the control of the water. Instead of the drenching rains being suffered to wash away fine particles of soil, manure, lime, or ash down the hillsides, the water is caught in carrier-canals and reservoirs, conducted along the sides of the declivities, and made to trickle down over water-meadows, or, with soil in suspension, allowed to rush over the surface where wanted, or else employed to turn mill-wheels and machinery at the farm-steads.

This leads us to notice very briefly the subject of *Irrigation.*—The object to be obtained is to flood the land at pleasure in such a manner as to maintain an incessant shallow flow or trickling amongst the blades of herbage. To give the surface the requisite inclination in every part, to design and lay out the *carriers* which bring the water, and the intervening drains which convey away the spent floods, according to the levels of the land, and have the water under perfect command, requires very considerable knowledge and judgment. The water is to run in the months of October, November, December, and January, from fifteen to twenty days at a time, with intervals of five or six days for the ground to dry and air. The question as to what water is suited or not for the purpose, is also one of some difficulty.

The Duke of Portland's water-meadows at Clipstone Park, in Nottinghamshire, are the most famous in England: many miles of a swampy valley, thick set with hassocks and rushes, the favourite haunt of wild-ducks and snipes; hillsides covered with gorse and heather; and a rabbit-warren, over which a few poor sheep wandered, having been changed into a succession of the richest meadows, producing a marvellous quantity of green cuttings and pasturage.

The Scottish moors are too frequent and extensive to be particularised. The moor of Rannoch, in the neighbourhood of Ben Nevis, includes a vast tract of rocks, lakes, and morasses, elevated about 1000 feet above the level of the sea, and is one of the most dreary, wild, and worthless districts imaginable. It is not inhabited, and seldom even visited. There is a somewhat similar district on the west coast of Cromarty and Sutherland; though without any great hills, and not very elevated, it is extremely rugged, bleak, and miserable. The soil of most of the Scotch moors, as well as of many of the mountains, is peat. On the granite formation, the soil is thin and poor, and situated in a cold bleak climate. It is of no agricultural value, so far as the production of corn and roots is concerned, and is covered with heather and coarse grass. On the whinstone or trap hills, the soil is of a very light character, and was first improved by the introduction of bone-manure, so that now oats and turnips are grown nearly 1000 feet above the level of the sea. In the Highlands, prodigious improvements have been made by clearing moors of stones, burning heather, extensive planting, draining mosses by open ditches, collecting and distributing the water along the hills by means of artificial canals; and improving the natural grass growing upon a thin soil, by draining and by grazing with sheep.

The most extensive of the *heaths and sands* of England are those of Surrey, Dorset, Hants, and some other counties, as Norfolk and Suffolk. The heaths of Surrey, particularly that of Bagshot, consist of a sterile and apparently unimprovable sand, for the most part level, but elevated between 400 and 500 feet above the sea. Only a few patches of good loam are to be found; so that the district will probably remain worthless, in an agricultural point of view, and its products be confined to a growth of heath, gorse, fern, and to a few plantations of larch and Scotch fir. 'On Bradley Common,' says Mr Evershed (*Royal Agricultural Society's Journal*), 'an extent of more than 100 acres is being reclaimed at an expense of £7 or £8 per acre; but it appears doubtful if the larch and fir which have been planted will thrive. The process of breaking up the ground consists in paring, burning the heath, and trenching, by spade and pick, to the depth of twenty inches, or more, according to circumstances. This depth is generally sufficient to break through the "iron crust," which is invariably found below the surface of the sand, and which, being impervious to water, is the cause of the heath's being frequently wet and boggy.'

The heaths in Dorsetshire and Hampshire are very extensive. In the former county, plots of twenty or thirty acres are taken at nominal rents by small farmers

for reclamation. Mr Ruegg (*Royal Agricultural Journal*) says: 'The land is broken up with large mattocks, at a cost of £2 per acre; the surface is either burnt or worked about until the turf decomposes. The next process, chalking, is very expensive; as they go from three to five miles for the chalk, and though it costs at the pit only 6d. a ton, its cost on the land is £3 an acre. It might pay to sink a shaft, as they do in Hampshire. The general dressing is twenty tons an acre; but on sandy soil this is thought too much. It is worked down with Crosskill's clod-crusher, and scarified, and sown with turnips or rape. It is well dunged, and two or three good crops are taken from it, but at a heavy cost. The green crop is eaten off, and very large crops of oats obtained—as many as sixty or seventy bushels per acre.'

The chalk *Downs* of our southern counties remain to be noticed—including Salisbury Plain, in Wiltshire—an elevated table-land, with a thin, light, and flinty soil, covered by a fine greensward. In Dorsetshire, a very great extent is being broken up every year; and land but lately the habitation of foxes and rabbits, producing furze, fern, and a scanty portion of sheep-feed, with a return of only 2s. 6d. an acre, is now yielding £1. Breast-ploughing and burning the turf is the first operation; and after a crop of rape, wheat, and clover has been taken, the land receives an application of chalk.

Although it might not pay the farmer to break up very lofty, steep downs, having scarcely any soil, still thousands of acres in Sussex, Wilts, and other counties, now depastured by flocks of sheep folded on arable land at night, and extensive tracts, producing little but heath and furze, might be brought into profitable tillage, and made to yield in saintfoin, clover, and other artificial grasses, an amount of food immensely greater than that afforded by the natural herbage. Many trials have been commenced, and afterwards abandoned, by those who neglected the principle that the soil has to be made, and enriched by manures and green crops fed off with sheep, instead of immediately taxed with corn cropping; whereas, there are innumerable instances to shew that light chalk-lands, as well as other wastes, will prove worth reclaiming, if only persevered with: tillage and the application of mineral and animal manures, for a course of years, having the effect of creating a good soil where scarcely any existed before.

The basis of improvement in light, silicious soils, is the application of chalk, marl, or clay; this admixture giving greater solidity and retentiveness for moisture, a power to arrest and retain organic riches from the atmosphere, while supplying many mineral substances required in the constitution of a fertile soil.

Marling and Chalking.—*Marl* is a term applied in different localities to a variety of earths, generally consisting of a mixture of clay, sand, and lime, but also including such substances as red or blue clay of an unctuous or pulverulent character. Marl-beds are found in hollows at the foot of hills, at the bottom of ancient lakes, below peat-mosses; particularly in districts where chalk-hills, limestone rocks, or spring-waters containing much lime in solution, abound. *Clay-marl*, used in Norfolk and Suffolk, is the *till* of the diluvial or drift deposits, consisting of blue and yellow clay containing lumps of chalk. A common dressing upon gravelly or sandy land is from forty to seventy cubic yards per acre. The cost of filling and spreading is about 3d. per yard; and of the cartage, according to the distance. *Shell-marl* is a kind found under bogs and mosses, and at the bottom of most dried-up lakes, and is evidently a calcareous earth, formed of decomposed testaceous fish.

Chalk is employed as a manure and mechanical solidifier of light soils, in every locality where it exists, and has been the chief agent in improving the thin, flinty loam of the Lincolnshire wolds. It is there excavated from pits or quarries, and carted upon the land at an expense of 5d. or 6d. per cubic yard. A dressing of 80 to 100 cubic yards is applied per acre; the chalk is weathered by exposure to a winter's frost, and then crumbled down by harrowing. On the Chiltern Hills of Buckinghamshire, pits or wells are sunk in the fields, about twenty feet deep, and the chalk drawn up in baskets by a wheel. A load of sixteen bushels costs 5d. for digging, drawing, and barrowing out; 3s. per 100 loads is charged for spreading, and 4s. per 100 loads for levelling-in the pits.

MOSS-LANDS, FENS, AND MARSHES.

Peat-mosses are supposed in some cases to have been occasioned by the destruction of ancient forests, either by the hatchet or from natural decay. In other cases, bogs have been formed by aquatic plants vegetating in hollows, holding water; mud accumulating round their roots and stalks, formed a semi-fluid mass, which increasing gradually, filled up the hollows, so that sphagnum and other mosses could grow. The peat which has been formed in this manner is therefore a compound of vegetable substance not entirely decomposed; commonly enclosing decayed trees, of pine, birch, hazel, or oak. The lowest layers of peat are commonly formed of aquatic plants; the next, of mosses; and the highest, of heath. The quality of the bog may be judged of from the plants which grow upon it: on ground completely saturated with water, various species of moss grow, to the total exclusion of other plants; but if the land should in any way become drier, reeds, rushes, and other plants spring up in the place of the moss; and all the moss-tribe, the horsetail and the marsh trefoil, are fibrous, and difficult to decompose; while reeds, rushes, and sedge are comparatively easy of decomposition.

Morasses abound in all mountain and moorland districts, particularly in Scotland; while extensive tracts of flat mosses and peaty land are found in Lancashire, the fen-country of Cambridgeshire and Lincolnshire, and in Somersetshire. In Ireland, the mountain peat occupies 1,300,000 acres, and the flat or red bog, 1,600,000 acres, including the extensive tract, known as the Bog of Allen.

The following are examples of successful undertakings upon various descriptions both of the flat or red bog and the black or hill peat.

The reclamation of a large portion of Chat-moss, in Lancashire, was commenced by Mr Roscoe of Liverpool, and has been subsequently prosecuted with success. Drainage—the first step to improvement—was effected by cutting open parallel ditches 66 yards apart, 4 feet wide at the top, and sloping down to about 14 inches at the bottom, 3 feet 6 inches deep. In a wet floating mass like this moss, it was not possible to sink the ditch to the whole depth at once; and the first two spits being taken out, it was then left for time to consolidate the surface. The covered cross-drains, 10 yards apart, laid 3 feet deep, and running into the open ditches, were commenced; but in forming these, as well as the open drains, it was necessary to allow some time to elapse between the different operations, that the water might to some extent run off; the hollow drains being made by the top sod, dried by exposure to the air, being wedged into the open cut, and the peat thrown in again upon that to fill up. When the surface was partially dried, the heath and other plants growing upon it were set on fire, and burned off as closely as possible; and by ploughing and cross-ploughing, and cutting up the sods by a roller armed with knives, the tough and elastic character of the surface was destroyed. Both men and horses were obliged to work with pattens or flat pieces of wood attached to their feet. After this process, marl—found at the southern edge of the moss—was laid on the top, by means of a movable railway; the dressing being 100 cubic yards to the acre—equal to about one inch covering over the whole surface—and the average distance which the marl had to be removed,

about two-thirds of a mile. Town-manure was brought by the Liverpool and Manchester Railway—a mixture of night-soil and ashes being preferable to anything else; and by growing a crop of potatoes in the first instance, the different particles of moss-earth and manure became so thoroughly blended together that the soil formed would produce anything, and wheat, clover, and oats followed each other in successful rotation. After-experience has shewn that turnips, oats, and potatoes are the best crops for such land; and an admixture of lime and salt answers better than the bulky marl for destroying the vegetable fibre, converting the moss into friable mould, and preparing it for a first crop of potatoes. On the extensive mosses in the Fylde district of the same county, oats and potatoes, turnips, and even wheat, may be seen growing on the surface of bog perhaps thirty feet or more in depth; and, indeed, to cultivate a bog is a much less difficult task than to improve a moor; because the peat is only an excess of manure more readily destroyed than created. Main drains are first made conformably to the extent, configuration, and situation of the moss, to the levels of surrounding lands, and to the levels of the substratum on which the moss rests. Roads are formed by first cutting open drains on each side, and throwing the material into the centre of the intended roadway; and when this is tolerably dry, sand or gravel is laid on several inches thick, and four yards wide. Open ditches are made, dividing the land into fields of about four acres each, and covered drains are laid at ten-yard intervals. These are wedge-drains, similar to those of Chat-moss, and are three feet deep. The whole expense of draining each field of four acres amounts to about £1, 6s., to which must be added a share of the outlay for the general main drain or canal, and for roads. Marl to the extent of 100 or 110 tons per acre, is then applied by a portable railway, at a further expense of about £1, 14s. per acre. The value of the land thus reclaimed is often more than £1 per acre to rent, and is calculated to pay more than 10 per cent. on the outlay.

Some of the most unpromising bogs in Ireland have been converted into fertile soil, most commonly at an expense of about £15 per acre; though some have cost nearly double, and others, again, only £8 or £10—so much depending upon local circumstances, facilities for discharging the drain-water, and the distance of the marl, or other solidifying material, or the lime, which is so efficacious in altering their qualities. Black or mountain peat is generally situated favourably for drainage; and if marl, sand, or clay is not obtainable, and even lime cannot be procured, paring, and burning, and manuring will be found to produce, in time, a soil capable of bearing good crops; and this is the case even at very great altitudes, provided the reclaimer be content with rape or hardy turnips and grass-seeds for sheep-feeding, instead of trying to grow corn.

We have not space to describe the great drainages of our fens by embanking rivers, excavating straight instead of circuitous channels, lifting up the drain-waters from the low-lying lands by wind-mills and steam-engines, enclosing the muddy sands of estuaries and salt-marshes along the coasts from the sedimentary tides, and issuing the drain-water through sluices with self-acting valve-doors to keep out the sea. Tracts of open marsh deposited by the ocean still exist on the English coast, which it might be worth while to embank; in Ireland, there are some very fine *slobs*, as they are there called; and in South Wales, there are 11,000 acres of fen and marsh land, which, if drained, could be made into very excellent soil. We must allude, however, to a method of improving low flat land lying contiguous to tidal rivers or estuaries, and below the level of the tides at high-water—called

Warping.—The waters of the Ouse, Trent, and other tidal rivers converging to the Humber, hold in suspension a large amount of earthy sediment, locally termed *warp*, and by being conducted over the land, and allowed to deposit their slime, have covered some 20,000 acres of worthless peat-moor and weak sand with the richest possible soil. A sluice with opening doors is erected in the bank of the stream, a main-drain cut and embanked across the low lands to the ground intended to be warped; and the latter is surrounded with a well-sloped bank, sufficiently high to hold the water. The 'compartment' may be fifty acres or less—being so much as the farmer can conveniently spare at one time. The thick water enters the enclosure at the furthest side, and directly it expands into a quieter current, begins to let fall the deposit, passing slowly over the surface of the land on its way to the near side of the compartment, where a tunnel permits its escape back again into the drain at ebb-tide. The further side having received a sufficient coating, *inlets* are cut in the bank of the drain at a less-advanced position, until the water gradually silts up the entire enclosure. From one to three feet thickness of deposit is obtained in from one to two and a half years, according to circumstances; the expense, with large drains, and other works included, ranging from £12 to £20 per acre; while on land adjoining the public warping-drains, it is much less than half that sum. When the new warp has become partially solidified, furrows are dug in it; and after being exposed to a winter's frost, seeds are sown, with oats to shelter them. These are grazed with sheep for two years, when the excess of salt having drained out of the soil, beans, wheat, potatoes, and flax follow. This alluvial soil, rich in organic matter, is most prolific—worth £60 to £100 per acre—and commanding a rental of £2, 10s. or £3, or even much more.

The same kind of silt or warp is sometimes excavated from old river-channels, and by means of a movable railway, spread upon the boggy land to be improved.

In the Cambridgeshire and other fens, the peaty soil is improved by

Claying.—Pits are sunk in rows, say fourteen or fifteen yards apart; and on reaching the blue calcareous and greasy clay, at a depth of two to six or more feet, the workman casts out some two to four *draws*, throwing part on each side: the black soil removed in sinking the next adjoining pit is thrown into the last to fill it up; and so on, across the field. The object in sinking pits is to prevent the sides from coming together, which would be the case if a long open trench were dug.

CLAYS AND OTHER WET LANDS.

Our subject does not include the general agricultural improvement, by under-draining and other means, of ground already in cultivation; but there exist, scattered throughout the kingdom, so many tracts of almost profitless heavy land, whether in common or enclosed, that we must say a word as to the best methods of rendering them serviceable. Clays are inherently fertile, but mechanically difficult to manage: deep and effective drainage, deep tillage, a thorough exposure of the pulverised soil to atmospheric enrichment, and manuring with green crops ploughed in, in most cases liming, and in many burning the clay, are the principal features of heavy-land amelioration. Mr Smith of Deanston taught us to break up the subsoil, in order to deepen the staple gradually, to open a passage for the descent of water, air, and the roots of our cropping, to render the land drier, warmer, and more suitable for vegetation. But as there was a prejudice against bringing up a bad subsoil to damage the upper cultivated stratum, only a stirring and crumbling share was used—as it were, a horse-pick breaking up without raising the under stratum. Now, however, it is proved that we may trench—that is, raise the under-soil into perpetual exposure upon the surface, with the best possible results. The Marquis of Tweeddale's experience at Yester in East Lothian is very remarkable on this

point. The form of the share of his subsoil trench-plough to follow in the furrow made by the common plough, is shewn in the following cut. Fig. 25 is a plan,

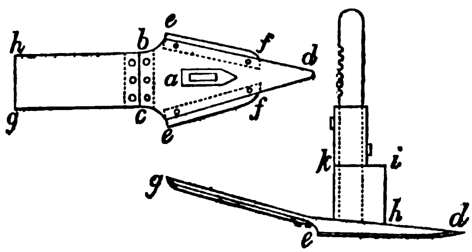

Fig. 25. Fig. 26.

and fig. 26 an elevation; *a* is the place of insertion of the coulter or stem. The sock, or share, is twenty-four inches long from *d* to *bc*, and fourteen inches wide. Two steel cutters, *ef*, *ef*, are fixed on each edge; and a tail-piece, *bcgh*, eighteen inches long and seven broad, is attached behind—sloping upward, so as to raise and pulverise the soil, and thus mingle it with the upper staple. The other figure represents Cotgreave's plough, manufactured by Ransomes and Sims of Ipswich,

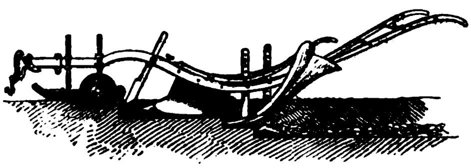

Fig. 27.

in which an ordinary plough is combined with a cutter and curved incline, which raise a portion of subsoil, and deposit it upon the top of the furrow-slice just turned over; while a coulter or cutter follows, at pleasure, to further break up the bottom. This implement promises to be invaluable in the work of heavy-land amelioration, or the intermingling of peat-soil with underlying clay—as practised in the fens—while other subsoiling ploughs, which simply break up without lifting, will be useful in destroying the hard pan under sandy soils, in disintegrating limestone rock, &c.

Mr Stephens's little book on the *Yester Deep Land-culture* contains a most admirable account of the improvements there effected on a large scale by draining and subsoil-trenching.

WOODS AND FORESTS.

Undoubtedly a very great extent of the royal forests and other wood-lands might be profitably grubbed up, and the land brought into cultivation. Wychwood, in Oxfordshire, about 4000 acres, has just been de-afforested, having previously produced for the country only £100 clear annual return; though the soil is well adapted for tillage.

Exclusive of Windsor, the fourteen royal forests lying in various counties from Hants to Durham, cover at least 48,000 acres, capable of yielding a princely revenue, if properly planted, thinned, and generally managed; but having really produced, until very lately, little or nothing.

The New Forest is a tract of 66,000 acres, of which little more than a quarter were wood-land in 1849. Half the land consists of most excellent soil, the remainder being poor, barren, and worthless. Until very late years, there has been an annual deficiency, though the property ought to return at least £60,000 a year. In Nottinghamshire, Mr Evelyn Denison has grubbed up some extensive oak-woods growing on a red-clay soil, at a total expense of £17 per acre, and has found that in every case the timber, &c., upon the ground defrayed the entire expense, and left a surplus of £5 to £12 per acre—the increased annual value being about £1, 4s. per acre. Many thousand acres of our national forest-land might be similarly treated with the same advantage.

But besides bringing woods and forests into cultivation, immense quantities of land may be added to our present arable and pasture, by the simple removal of useless fences, and curtailing the dimensions of those which are really requisite and necessary. Thus, around Exeter, the loss of land from the size and number of hedgerows amounts to no less than one acre out of ten; and in some districts of Norfolk, again, a like proportion of ground is thus wasted.

SPADE-HUSBANDRY.

Fig. 28.

The reclaiming and culture of small pieces of land by means of the spade and other instruments of manual labour, is usually spoken of under the name of spade-husbandry, but is also sometimes called cottage-farming or field-gardening—the operations of the culturist bearing an intimate resemblance to those applied in ordinary kinds of gardening.

It is very common for persons to argue against the practicability or advantage of settling the poor and hard-worked or out-of-work population on tracts of waste land—say in cottages with twenty acres, ten acres, or considerably less, to each family, assuming as the basis of their calculation that the cottager would make no more return from the same area of surface than the farmer who tries reclamation on a great scale. But innumerable facts contradict this assumption. Thus, the cultivation of the Bagshot sands has been attempted by many practical farmers, and afterwards abandoned; but it is a fact, that when the labourer puts his spade into this soil, he almost invariably succeeds in turning it into good potato-ground.

In his *Report on the Farming of Cornwall*, Mr Karkeek says: 'As a proof that a large part of the granite waste in the Land's End district would pay an almost immediate profit to the cultivator, I have only to state that a very considerable extent is now in progress of reclamation by cottagers, who obtain small plots of waste on leases of three lives, which they cultivate and build cottages on. When not very rocky or boggy, the land may be reclaimed at £5 to £6 per

acre—fencing not included, which varies according to circumstances. On taking ground of this description into cultivation for the first time, the cottager does not attempt to grow wheat, but potatoes and oats; in the course of five or six years he introduces barley; and in ten or twelve years, wheat. . . . . An immense breadth of waste on the slate-formation has also been reclaimed by cottagers, chiefly miners. The soil is exceedingly thin, resting on red or yellow gritty clay and coarse slates, abounding in quartz fragments, and traversed by mineral lodes and elvan rocks in every direction. The late Earl of Falmouth and Lord de Dunstanville gave a great impetus towards the reclaiming of this coarse kind of land, by granting pieces from three to five acres to cottagers on leases of three lives, at a small rent of from 2s. 6d. to 5s. per acre, on condition of their building cottages on the holding. The parish value of these lots now averages from 10s. to 20s. per acre. The Earl of Falmouth has nearly 2000 tenements of this description, which have increased in value, since 1815, from 20 to 25 per cent.' It is supposed that no less than 6000 working-miners are possessed of cottages on land which they have reclaimed.

In one district of Lincolnshire, called the Isle of Axholme, the occupations are remarkably small, a great number of farms being under ten acres in extent, while single acres, half-acres, and even roods are general over large tracts of open-field land. The soil is a very rich sand-loam, managed chiefly by the spade, hoe, and fork, and yields abundant crops to the constant and complete tillage and cleaning which it receives. Potatoes, onions, and other garden produce form a large proportion of the cropping. Many of these small cultivators may be poor, especially those who, having been too eager for a plot of land, have borrowed too large a proportion of the necessary capital, and so fallen into the clutches of mortgagees; but as a general rule they are well off, earning an independent though frugal livelihood. Perhaps one-fourth of them are owners; and there is a constant emulation among the remaining occupiers to become proprietors by a thrifty industry, great prices being consequently given for small plots of land. On the rich soils of the Isle, where toil is the principal requisite in cultivation, an industrious family succeeds well in spade-husbandry; though on light lands, needing the trampling of the flock and the expenditure of heavy sums in artificial manuring, the man whose chief capital is in his sinews would be at every disadvantage; though even there it is found that, by taking an acre or so of garden-ground, the labourer is amply benefited.

And if these examples are insufficient to shew the desirableness of extending cottage-farming and spade-husbandry, we have only to refer to the prosperous cultivators of Belgium and Flanders on this system—distinguishing between the industrious habits and skilful husbandry, both in tillage, rotation of crops, and manuring, found in those countries, and the absence of these essentials of success in so many parts of Ireland, where small-farming does not preclude poverty.

We will now consider the general management and practical details of cottage-farming. The homestead is to consist of a cottage with several apartments, which, with every convenience of copper, oven, well, outhouse, &c., can be erected for £70 or £80; a cow-house, pigsty, and barn. The size of the farm is supposed to vary from three to six, eight, or more acres, according to the capital and amount of labour which the occupier possesses, and to be laid out in a suitable number of field-plots by proper fences. If the land be in a waste condition, it must be cleared and drained. If moss, dig open drains round it to draw off the water; scarify the surface with the spade, and burn the heaps of turf; scatter the ashes over the land, with any sandy material or lime which can be procured, and then delve all from one end to the other. If the land be choked with stones or roots, all these must be removed to the depth to which the after-digging will have to go. In the case of strong or clay land, under-drainage will be necessary; and this is easily effected in small plots of land, when there exists an adequate outfall, by burying broken stones, thorn-fagots, &c., in drains three or four feet deep and moderately near together.

The tools required by the cottage-farmer are simple and inexpensive. They consist of two or three spades of different sizes; one or two of the light steel digging-forks now manufactured, which wonderfully reduce the labour of delving soil that has been stirred before; a pickaxe, hoes, rakes, scythe, reaping-hooks, hay-forks, flail, wheel-barrow, &c., according to means. A grinding-stone and a few carpenters' tools are also exceedingly useful. No horse or paid servant is kept, all the work being supposed to be done by the manual labour of the farmer and his family. The live-stock consists of a cow or cows, pigs, and poultry. To preserve manure without waste, a pit should be provided adjoining the cow-house, into which all the solid refuse and all that may be collected from the dwelling-house is to be removed. Liquid manure, and the drainings from the cow-house, &c., should be collected in a barrel sunk in the ground, and protected from the air. This is a most valuable liquid for throwing over the land to feed a young growing crop, especially for grass, &c., mown for the cow. A few shovelfuls of earth must be laid upon the solid manure whenever a layer of it is added to the quantity in the pit, so as to arrest the escape of any volatile and offensive gases during the process of partial fermentation. Rubbish of all kinds, withered leaves, stalks, clippings of branches, roots, &c., should be gathered into a heap, and occasionally moistened with urine from the cow-house, or mixed with a little lime, so as to rot down into valuable manure.

Whether it would be preferable to devote a cottage-farm to a mixture of green and grain crops, as in ordinary husbandry, or make it chiefly a dairy-farm, in which the raising of green crops for fodder is the main object, must depend on local circumstances. Generally speaking, it will be found advisable to make the maintenance of the cows the principal object, the crops consisting of rye, lucerne, clover, Italian rye-grass, cabbage, tares, mangel-wurzel, turnips, wheat, and oats; the cows being kept on straw and roots in winter, and upon green fodder mown for them during the summer. Of course, the animals must not be allowed to graze on any portion of the artificial grass crops; but being fed in a shed or lodge, may have a small open space in which to move about for their health. It is found that not only the cow gives a great deal more milk when kept warm in a house, but that the land yields a much larger proportion of food for her than when she is suffered to depasture and trample it. Indeed, three roods, or half an acre of artificial grasses, according to the application of liquid manure to the surface after each cutting, will suffice to keep one cow. There may be more than one crop in a year on part of the land: say that rye is the first thing cut green in spring, dig the land, manure, and sow mangel and turnips; the next cutting is of winter barley and tares, which are to be followed by late-sown turnips and planted cabbages; and the Italian rye-grass and clover yield several successive cuttings in the course of a summer, by plentiful waterings with liquid manure.

A portion of ground is to be set apart as a garden for potatoes, parsnips, carrots, onions, cabbage, and various table-vegetables; a few currant and gooseberry bushes, and an apple-tree or two, a few flowers near the house, and perhaps a hive of bees, not being forgotten.

From many reasons, the spade is found to be a far more efficient cultivator than the plough; the soil is not only deeply broken up, for the penetration of the roots of plants and for the admission of fertilising rain-water and atmospheric air from which the soil is

continually absorbing gaseous nutriment for crops, but it is more completely subdivided and pulverised; there is no glazed pan, as left by the sliding pressure of the plough, to oppose the descent of rootlets, of water and air; and by the more accurate inversion of the soil, the seeds of weeds and larvæ of insects which are about the surface are turned down and destroyed. The greatest advantage of spade-husbandry is in the trenching or very deep digging which can be practised. Instead of recruiting the productive power of the land by fallowing, as in ordinary farming, the cottage-husbandman brings up an under-stratum of soil to take the place of that which has been bearing a crop upon the surface. This layer, which we may call No. 2, lies, say from nine to eighteen inches below the surface, supposing a nine or ten inch spade to have been employed in the ordinary digging. After two or three years' cropping, a considerable portion of the manure delved in will have been washed down and imbibed by this lower stratum, and the upper layer will have been largely robbed of the mineral ingredients necessary for the sustenance of good crops. The art, then, consists of raising up this layer, No. 2, and turning down No. 1 in its stead. In some districts, the depth of available soil may not be so much as eighteen inches, the layer beneath being rock or chalk; in which case it will often be worth while to expend great labour in gradually breaking it up with the pick, and incorporating portions of it with the upper soil. Indeed, in no case is it advisable to bury the top staple at once, and attempt to grow a crop upon the raw, unmitigated, unameliorated subsoil brought up in its place; the principle is, to deepen gradually, bit by bit, and so, in effect, add to the extent of land cultivated without increasing the superficial area.

The Rev. Mr Smith, of Lois-Weedon, Northamptonshire, obtains immense crops by following this principle, together with that of having fallow-intervals between the rows of cropping. By deeply burying farm-yard manure, and well dressing with guano, superphosphate of lime, &c., beside, he produces thirty-eight bushels of winter beans and fourteen tons of carrots upon the same acre of land—the beans being in single rows, no less than five feet apart, and the carrots in rows between. This he finds very profitable; and besides interlining various other root or green crops with success, he grows wheat without a particle of manure year after year upon the same fields, with an average yield of thirty-four bushels per acre, and a profit of £5 per acre, with wheat at £2 per quarter. The wheat is in triple rows, one foot apart in the rows, with intervals of three feet. The intervals are dug two spits deep before winter, scarified in spring, and horse-hoed through the summer; this stirring being found to feed the corn-plants growing on each side, as well as prepare a fine and fertile seed-bed for the rows of wheat the following year. The wheat-rows and fallow-intervals succeed each other alternately, the same strip being thus bare-fallowed every other year; and it is found from a long course of years, both on clay and gravelly land, that the annual produce, reckoned for the whole field, equals that which other farmers obtain only once in two years. The cottage-farmer will do well to make himself acquainted with the particular directions laid down in Mr Smith's pamphlet, the *Word in Season*, and in his little book entitled *Lois-Weedon Husbandry*, as we believe tillage, such as that which a small occupier can accomplish with facility, has never before been brought to produce such remarkable returns, alike in produce and in a cleanly condition of the land.

In working a cottage-farm, unremitting industry is required; and it should be an object to make the very most of every day out of doors when the season and weather permit, and to occupy the dead of winter and days of bad weather at work in the barn or house. Trenching an acre two spits deep will take from thirty to thirty-five days; and one-spit digging ten inches deep, from twenty to twenty-five days, according to the nature of the soil. To make ridges for potatoes, plant the sets, mould them up with the hoe, and finally take them up, will take about twenty-four days for one acre. In digging, it should be borne in mind that a man can effect about one-sixth more work with a proper steel fork than he can with an ordinary spade.

In a report of the Emigration Committee, published some years ago by the House of Commons, is the following estimate of the expense attendant upon the location of a family, consisting of a man, his wife, and three children, upon four acres of waste land fit for cultivation, in any part of the United Kingdom:

	£	s.	d.
Transport of the Family—say, on an average, 50 miles—to their location,	3	0	0
Implements,	2	10	0
Household Furniture,	5	0	0
Cottage, Cow-shed, and Pigsty,	26	0	0
Potatoes and Seed,	4	0	0
Provisions for one year,	25	0	0
Cow, Pig, and Poultry,	9	0	0
Proportion of the Cost of Superintendence,	0	10	0
	£75	0	0

The items for the buildings and the live-stock are much too low for the present day, so that £100 will be nearer the sum required. It was considered that by the produce of the four acres cultivated by the spade, the family could maintain themselves, and, after a lapse of five to seven years, dispose of produce to the value of £22 per annum, after paying £8 yearly rent.

A cottager is described, in the *Cottage Farmer's Assistant*, as keeping two cows upon three acres of light land in Sussex, with the following results:

					£	s.	d.
278 pounds of butter, in 6½ months, sold at 1s. per pound,					13	18	0
Skim-milk, sold for 3 pints 1d., or given to the pigs, estimated for the year at					10	0	0
Two Calves, sold for					5	18	0
Half an acre and 8 rods of land, yielding 19 bushels of wheat, at 8s.,					7	12	0
A quarter of an acre, producing 14 bushels of oats, at 4s.,					2	16	0
Making a gross produce off half an acre of pasture, and 2½ acres of arable, of					40	4	0
Rent, Taxes, and Tithes,	£12	12	6				
Seed,	2	0	0		16	12	6
Hired Labour,	2	0	0				
Making a clear profit of					£23	11	6

And the butter looked for in the remaining five-and-a-half months was expected to make a total gain, from the labour of the cottager and his wife, of £30.

We have not space to enter upon the subject of the use of the spade in conjunction with the plough on farms large enough to support a team of horses; but it is placed beyond a doubt, that more produce is raised for human subsistence—space, soil, and climate being equal—by small farmers using only manual labour, than by large farmers with horses and ploughs.

In these days of farming-capitalists, and the appliance of steam-power, not only to mill-work, but the tillage of estates, the claims of the poor to a share of land, and to independence, as a prospective reward for their industry, are not very likely to be remembered; but if it be true that the system of large tenancies, and still more of monopolised proprietorship, has not been able to prevent a decrease of our rural population, and an immense amount of pauperism, it becomes high time for the community to demand that the waste grounds be utilised, and the people provided with the means of earning an honourable livelihood in that healthy and ever-coveted employment—the culture of the soil.

THE KITCHEN-GARDEN.

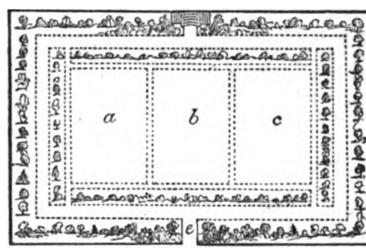
GARDENING, whether regarded as an ornamental art, or as a branch of industry, has long been cultivated with success in the British Islands, and has, in fact, become more intimately identified with the English people than with any other nation. Happily, many advantages of a public kind are now afforded for the gratification of our love of gardening. The Royal Garden of Kew, the model-garden of the world, is now the everyday resort of pleasuring parties of all ranks of society—from the humble artisan, whose holiday comes once a year, to the rich noble, whose life is one long holiday. The Crystal Palace at Sydenham, the Regent's Park Botanic Garden, and the 'marine gardens' (vivaria) of the Zoological Society, are additional sources of delight to all lovers of gardening in London; while the inhabitants of Scotland have the Royal Botanic Garden at Edinburgh, with its new palm-house and noble heaths and ferns, the Experimental Garden of the Caledonian Horticultural Society, and the Botanic Garden at Glasgow. Ireland is fortunate in its Botanic Gardens at Dublin, Belfast, and Galway. The provincial public institutions of this kind in England are numerous—as those at Cambridge, Oxford, Sheffield, Manchester, &c. But the possession of such public gardens does not satisfy the people; for gardens are like libraries—the enjoyment of a public one leads every man to wish for a little paradise of his own.

There are various kinds of gardens—the Italian gardens, with their splendid terraces, vases, and statues; the old French gardens of Le Notre, of which we have a specimen at Versailles, with their long straight walks, clipped hedges, formal parterres, and fountains; English gardens, with their elegant blending of natural with artificial beauty; and so on. But it is to none of these princely kinds of gardens that we intend, in the present series, to direct attention. We propose to treat of the three departments which belong to the greater number of gardens of the middle and humbler classes; those, in short, which, designed on a moderate scale, are intended to afford the three staples of garden culture—*vegetables* for the kitchen, *flowers* to charm the eye, and the more easily attainable kinds of *fruit*. These various articles are for the greater part the production of one garden, a section or scattered part being set aside for each; but for the sake of clearness, we shall confine ourselves in the present sheet chiefly to the economy and products of the kitchen-garden.

CHOICE OF SITUATION AND LAYING OUT OF GARDENS.

A garden of the ordinary mixed description varies from the eighth of an acre to a whole acre; but the most common size in country places is about half an acre. Whatever be the dimensions, the garden ought to be enclosed with a wall from ten to twelve feet high, and the ground thoroughly drained. Besides a wicket or small door for ordinary entrance and exit, there should be a gate that will admit a cart, to take away produce or bring in manure. A much more important circumstance than size or external appearance, is exposure. In a flat country, the garden must of course be level; but if there be a choice as to situation, select by all means a spot which lies with an easy slope—an angle, for instance, of fifteen degrees—towards the sun at his meridian. In the British Islands this will be facing the south. The next best exposure is towards the south-west, and after that the west. Avoid a northern or eastern exposure. An exposure towards the morning and mid-day sun, even though at a very small inclination, is as good as being many degrees further south; hoar-frost on the grass and plants will be melted within an hour after sunrise; whereas if the garden lie in the smallest degree away from the sun, the hoar-frost will remain unchanged perhaps the whole day. Allow no house, wall, or trees, to interrupt the fair action of the morning sun on your garden; for the sun is the main agent in bringing vegetation to perfection, and if you be deprived of it, your operations will be blighted and retarded in every possible way. So important are the sun's rays, that if your garden be small, rather have no wall on the south and west sides, but only a low fence, than submit to their exclusion. Some gardens are so disposed that they receive the sun in abundance in summer, but only partially the rest of the year. These gardens are imperfect. The garden should be visited all over by the sun daily, except perhaps in the heart of winter, when his rays have comparatively little effect. The exposure should also allow a free admission and currency of air; for this reason, a garden is best away from dense old woods, and is most advantageously placed in an open sloping lawn, overlooked by, or near the house of the proprietor. There should be an abundant supply of water readily at hand, for 'water is the life and soul of a garden.'

The shape of a garden is of little consequence. It may be square, oblong, semicircular, or irregular, according to taste or local circumstances. In the greater number of instances, an oblong, as represented in the following plan, will be found most convenient. It is surrounded



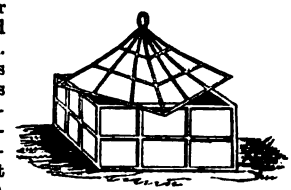
by a wall, in which is an entrance marked *e*. Within the wall is a border of several feet wide, and dotted round with flowers or flowering shrubs. Next is a gravel walk; and within is another border containing fruit-bushes, or perhaps fruit-trees on espaliers, and in the centre is the body of the garden laid out in three plots, marked *a*, *b*, and *c*. Between these plots and around them are paths (represented by dotted lines) of twelve or fourteen inches in width, not for ordinary walking, but for admission to the various plots or sections into which the ground may be divided. These paths are only flattened by the foot or by the spade, and are to be delved up annually in the course of digging. At the opposite side of the garden from the door there may be an arbour or summer-house fitted up according to taste, and overhung with honeysuckle, jasmine, or other climbers.

The regular walks in all moderately sized gardens should not be wider than three feet, at least where land is of value. Much care is required to keep walks in order, for they are very liable to shew crops of weeds and grass. To prevent this, as well as to guard against worms, which are very apt to disfigure the walks by throwing up casts, it is a good plan to bottom the walks well with broken cinders or slag from furnaces. Over a

smooth bed of this kind put a layer of small gravel that will bind, or, failing this, a layer of brayed yellow ashes from a furnace, if they can be procured. Smooth all with the rake, and flatten with a roller. Such walks should be scuffled with the Dutch hoe, raked, and rolled down several times during the season, otherwise the growth of weeds and moss will render them untidy. On no account should such operations be neglected until *Poa annua* and other grasses have shed their seeds, otherwise it will be impossible to get the walks thoroughly cleaned. Many small flowering plants—such as daisies, Virginian stock, thrift, and the spring potentilla—are used for edgings to walks; but if not constantly attended to, they straggle over the borders. The most effectual, and also the prettiest edging, is dwarf-box. It is easily planted in an even row, grows readily and regularly even under the shade of trees and amidst the smoke of a city, requires little trouble in trimming, and throughout summer and winter is ever fresh and green.

The above remarks will suffice to indicate the mode of forming walks in a common kitchen-garden of ordinary dimensions. Where the garden is more extensive, and is intended as much for ornament as utility, more care will be required, for nothing conduces so much to the tidy appearance and comfort of a garden as the neatness of its walks, especially in wet weather. Mr Glendinning has recently submitted some valuable suggestions on this subject to the Horticultural Society of London, to a few of which, notice may be called. In the first place, both verges or edgings of a walk should be of the same level, whether it be formed on level, ascending, descending, or unequal surface; by this arrangement, both sides will be equally affected by the rain, which so frequently disturbs the surface; and such walks are more agreeable than those having an inclination from one verge to another, and are more in keeping with the rules of good taste. To a refined eye, a walk whose verges follow natural inequalities of surface, resembles a building standing at a right angle to the sloping bank on which it is erected—after the manner of the leaning towers of Bologna. Good provision should be made for carrying off the rain, for which purpose, earthenware tubing is employed, of a diameter proportionate to the extent of walk to be drained. This is laid in the centre with communicating tubes to the sides, where square cess-pools, about 9 inches square and 18 inches deep, built in brickwork, should be formed to receive the water and sand, &c., a grating being placed over each cess-pool. Where the walk takes a precipitate fall, it will be necessary to have surface tile-gutters along both sides, or sea-pebbles may be used with good effect. The geological formation of the neighbourhood must be the guide as to the material to be employed in forming the walks. Broken stones, rubble, or clinkers, constitute a good foundation; a foundation of nine inches is sufficient. Concrete or asphalt is sometimes used for the surface; but good gravel, where obtainable, is to be preferred. 'It is more congenial to our feelings, and harmonises better with the surrounding scenery of the garden.' The surface of a walk should be nearly level, with only so much convexity as to readily throw off the surface-water.

No precise directions can be given respecting garden tools and apparatus; the following are the articles required in moderately sized gardens of a mixed kind: Spades, a trowel for lifting flowers, Dutch and common hoes, iron rakes, a strong clasp-knife for pruning, pruning-gloves, a pair of strong pruning-shears, an axe, a hand-saw, a hammer and cast-iron nails, a wheelbarrow, a roller, a dibble and line, a watering-pan, a ladder, flower-pots of different sizes, conical earthenware blanching-pots, bell-glasses, and glazed frames of different sizes. These frames may be had either in one piece or with a movable top, as in the following figure. A neat small kind, framed in zinc, useful for protecting early seedlings or flowers, may be had in London for 1s. 6d. each. Other utensils employed by gardeners—such as forcing-pumps to wash wall-trees, fumigating bellows, &c.—need not be particularised. A person possessing only a small garden will shortly discover by experience what are the articles required in his operations. The articles constantly in use are the spade and rake; with these alone many a small garden is successfully cultivated, and the amateur with whom economy is an object, will do well in entering for the first time upon a little garden of his own, to begin with the spade and rake, and allow experience to suggest further wants in the tool department. For gardens in which cucumbers and melons are to be grown, glazed frames and brick-built pits will be necessary. As already indicated, it is a great advantage for a garden to have a command of good fresh water for the purpose of irrigation, and also a small pond in which aquatic plants can be grown. If water is procured from a pump-well, it should be allowed to stand in the open air in a trough for at least a day before being poured on the plants. By this means it gradually acquires the temperature of the atmosphere.



A garden is in all cases laid out according to the taste or fancy of the proprietor; but there are certain general rules which all follow. The wall is reserved for fruit-trees. As fruit-trees require much air and sun, the borders must not be clogged up with bushes, peas, or any other tall vegetables. The borders should either be reserved entirely for the roots of the wall-trees, or contain only small articles which are delved up yearly, because the soil at the roots of the trees requires occasional renewal and loosening, and these operations cannot be done if the ground is encumbered with permanent plants. If a row of gooseberry or other small fruit-bushes be placed on the borders, they should be near the outside, and not less than ten feet apart. Let it be observed also, that flowering-plants should occupy the border most exposed to the sun; while horse-radish, and others naturally loving the shade, should be placed on the south and west borders, from which the sun's rays are generally less or more excluded.

The body of the garden within the walks is laid out in larger or smaller plots, according to taste. These plots are generally oblong, and are subdivided into sections, rows, or beds, for the different kinds of kitchen vegetables. In the corner of one plot are the cucumber and melon pits, partially secluded, but not shaded by hedges or bushes. In different corners are plots, and round the edgings are the flower-parterres, disposed to meet the eye, and to be easily accessible from the walks. In some gardens, much of the ground is overshadowed by fruit-trees. This is seriously detrimental to the growth of the plants beneath, exhausts the soil, and prevents the proper flowering and fructification of every vegetable within reach. Permit no tree to overshadow your ground; the only allowable places for trees are the walls and narrow espaliers running up one side of the central plots. When a garden possesses the addition of an outside strip, enclosed by a hedge, the exterior sides of the walls may be lined with fruit-trees, and the ground laid out for potatoes and other common vegetables; it will also afford the most proper site for compost dung-heaps, forcing-pits, and the like.

PREPARATION OF THE SOIL—COMPOSTS—TRENCHING.

The soil of a garden should be deep, rich, and easily penetrable. Whatever it may have been originally, the soil admits of vast improvement, and no trouble can be

considered too great to bring it into a good condition. If shallow, trench it so as to loosen the subsoil and gradually bring it into operation above. In many instances the soil is too stiff or clayey. Such a soil may not be unfit for plough husbandry, but it is out of place in a garden. The method of loosening and meliorating a clayey soil, is to give it a large volume of sand and vegetable manure, which may be delved in at the winter digging, and at the spring digging, the new and old materials will be well mixed. In general, too little attention is paid to adding sand as a restorative; such is absolutely necessary in all soils except those of a very sandy nature, because every crop actually carries away a certain proportion of the silica lodged in the soil. If the soil be already too sandy, it may be assisted by clay, silt from ditches, &c. Whatever be the nature of the soil, it should be thoroughly pulverised. Lumps thrown up by digging at the commencement of winter are pulverised by the frost, and imbibe nutritious gases from the atmosphere. In spring, all should be well delved, every spadeful being cut and broken as it is turned down, and no hard part left impervious to the tender roots of the vegetables. Every particle of soil should be capable of doing duty in feeding the plants.

No garden can be conducted with the least advantage without giving it regular manuring. If you hunger a garden, it will hunger you in return. In connection with every rightly managed garden, there must either be a compost heap, in which dung is preparing for use, or there must be some means of readily purchasing old manure when it is required. The manures employed are the same as in Agriculture; but being required for a more delicate purpose, they must in general be well rotted, and ready to unite with the soil. A compost dung-heap is prepared by putting alternate layers of stable-dung, or night-soil, &c., with earth, peat-moss, decayed leaves, and general refuse of vegetation, turning the whole occasionally till the mass appears to be sufficiently decomposed for use. A small quantity of this stuff will often be required to place at the roots of plants.

Near large towns, where there is a constant demand for kitchen vegetables, market-gardens are established for producing the required articles in variety and abundance. The finest market-gardens in the world are near London, where the soil is deep, and any quantity of manure, in the form of night-soil, from the metropolis, is easily obtainable. The plan on which these gardens are conducted might serve as a model for all kitchen-gardeners in this country. It is thus briefly described in the article Gardening in the *Penny Cyclopædia:* 'The gardeners' year properly begins in autumn, when the land is dug, or rather trenched, and well manured. Various vegetables, which will be required in winter, are now sown, and especially those which are to produce plants to be set out in spring: spinach, onions, radishes, and winter salads are sown, and when the weather is severe, are protected by a slight covering of straw or mats. In February, the cauliflowers, which have been raised in frames or under hand-glasses, are planted out. The cabbage-plants are pricked out. The radishes, onions, and salads go to market as soon as they are of sufficient size, and sugar-loaf cabbages succeed them. As the cauliflowers are taken off, they are succeeded by endive and celery, and the same is the case with the cabbages. Thus there is a constant succession of vegetables, without one moment's respite to the ground, which, in consequence of continual stirring and manuring, maintains its productive power. Deep trenching in some degree prevents that peculiar deterioration of the soil which would be the consequence of the frequent repetition of similar plants. This effect is most perceptible when the plants perfect their seed, which is seldom or never allowed to take place in market-gardens; but great attention is paid to the species of plants which succeed each other on the same spot. The principle which experience and theory unite in establishing, is that of avoiding the too frequent recurrence of plants which belong to the same natural families. The greater variety cultivated in gardens, in comparison with the common produce on a farm, enables this principle to be fully acted upon. Those gardeners who overlook this, and repeatedly sow or plant the same kind of vegetables in the same spots, are soon aware of their error by the diminution of the produce, both in quantity and quality, and by various diseases which attack the plants, however abundant may be the food supplied to them, or however careful the tillage.

'The principle on which the gardens are cultivated, is that of forcing vegetation by means of an abundant supply of dung, constant tillage, and occasional watering. . . . . Those vegetables which arrive at a marketable state in the least time are always the most profitable, and those also for which there is a constant demand at all times of the year. . . . .

'The value of the produce in one year from an acre of garden-ground in the most favourable situation, as stated by Mr Middleton, from the account which he received from a market-gardener, is almost incredible. It is as follows:—Radishes, £10; cauliflower, £60; cabbages, £30; celery (first crop), £50; (second crop), £40; endive, £30: making a total of £220 for the gross produce of an acre in twelve months. The expenses of cultivation are no doubt great. In inferior situations, the produce is much less, but the expenses are also somewhat less. When it is considered that there are nearly 2000 acres thus cultivated, the gross amount of produce must be very great.'

GENERAL OPERATIONS.

Digging or *delving* with the spade is the principal means of garden culture. The spade usually employed is ten inches deep in the blade or spit; but as delving is not direct downwards, but sloped, the depth to which the spade goes in digging is seldom more than nine, and often not more than eight inches. In commencing to dig a piece of ground, take out a spadeful all along one side, and carry it to the opposite side where you are to leave off. Now begin at one end of the trench just opened; thrust the spade with the foot into the ground, taking about five inches in breadth, lift it up, and turn it over into the open trench, the top undermost, and the fresh earth above. Do the same with the second spadeful; and so on with all the others to the end of the line. Take care to dig always a uniform depth and breadth, so as to keep the line even, and the trench or open furrow of one width. If there be any weeds or loose refuse on the surface, put them in the trench, and cover them in; where the ground is dirty, all such refuse ought to be well rotted in the dung-pit, or, what is better, reduced to ashes, and then spread over the soil. Break or pulverise the mould as you proceed, and keep the fresh surface level. When you have delved row after row to the last, the earth laid aside will fill up the concluding trench. Ordinary digging is performed best in dry weather; but digging to throw up lumps for winter melioration should, if possible, be performed when the soil is somewhat moist. In this kind of digging, do not touch the lumps with the spade after throwing them up; for the more rugged and uneven the surface, the more thorough is the exposure to the influence of the frost.

Raking.—Hold the handle of the rake at an angle of forty-five degrees, and draw it lightly over the surface of the newly dug ground. The object is not to draw earth along, but to smooth or comb down the irregular surface, and to bring away any loose refuse or stones. Like digging, it should be performed in dry weather.

Marking with the Line.—The gardener measures and marks off all his figures in the ground with his line and spade. With the line he can draw a circle round a

central pin, or make an oval from a union of two circles, or form semicircles, spirals, triangular spaces, or polygons. When he wishes to make a small path between rectangular plots, he sets his line accordingly, and walking along it, with a foot on each side, he tramples down the earth from one end to the other, and then he can smooth it and beat it down with his spade.

Hoeing.—With a common hoe, the earth is cut and drawn towards the operator. The object of hoeing is to draw up the earth so as to cover the lower parts of the stems of plants growing in a row. In hoeing weeds, which is done by a different implement, the Dutch hoe, cut off the weed beneath the surface, and do not cover the stalks, which are to be raked away, and placed on the dung-heap. Weeds, especially such as dandelion and groundsel, whose seeds become winged when ripe, should be hoed and removed before seeding. As many such weeds which infest gardens are blown into them from adjacent roadsides, it would not be misspent time to clear the neighbourhood periodically.

Animal Annoyances.—All gardens are more or less exposed to the destructive inroads of wild animals. Hares and rabbits not only gnaw the bark off the stems or lower branches of trees, and also the buds in season, but are also very destructive to vegetables and flowers. To prevent the encroachments of these quadrupeds, the garden ought to be properly fenced; but if they get in notwithstanding, the trees may be saved by smearing the lower parts with a mixture of cow-dung, soot, and water, reduced to the consistency of thin paint; a smearing of tar will also answer the purpose. Moles, rats, and mice may be caught by trapping; moles also are said to be got rid of by placing slices of garlic, or onion, in a green state, within their holes, as they have a great antipathy to the odour of these vegetables.

Birds are sometimes an annoyance, particularly when new-sown peas or seeds may be easily scratched up. But, though in some instances injurious, it is believed that on the whole their visits are beneficial; for they pick up large quantities of slugs, insects, larvæ, or caterpillars of different kinds. Wall-fruit may be preserved by nets, or by the more simple method of fixing horizontal lines of black worsted in front of the trees; the repeated ineffectual attempts to alight on these lines are said to scare the animals, and cause them to desist. Lines of threads, along which feathers are fastened, are employed in many cases to protect beds of seeds from birds, but are only partially successful.

Insects are the grand pest of gardeners; their appearance is so mysterious, and their devastations so varied, that all schemes to extirpate them are often ineffectual. They are most destructive in their first condition of larvæ or caterpillars. In this state they should be removed by the hand from kitchen vegetables. To destroy the smaller kinds of larvæ, fumigation of tobacco-smoke, by means of a fumigating bellows, may be employed with advantage; and the plants may be cleansed with a syringe and water. For the cleansing of fruit-trees from insects, we refer to our article on FRUIT-GARDENING.

Slugs are another chief annoyance, especially in low-lying shaded situations. A little salt destroys them; but, as in the case of caterpillars, the best plan is to clear them out on their first appearance, by the hand. Worms in the ground are not considered injurious. Salt kills them.

Sowing.—The greater number of garden vegetables are reared from seeds, which are sown at certain seasons in the ground. Some seeds, such as peas, are sown in drills, the hand deliberately dropping them in a straight shallow trench. Other seeds, such as those of onions, leeks, cress, &c., are sown broadcast, which is a thin and equable scattering over a bed prepared for the purpose. There is no necessity for any species of sowing-machine in a common kitchen-garden. Most seeds, peas included, require to be pressed down by treading or gentle rolling, and then covered up by the hoe or rake. All seeds should, if possible, be sown and covered up in dry weather.

Planting.—Many vegetables require to be removed while young from the bed in which they were grown from seeds, and planted out in rows. Having adjusted the line, commence at one end of it; pierce the earth with the dibble, and into the hole so made, insert the root of the plant, and pierce the earth at its side, so as to press the mould round the root, leaving no vacant space below. The common error in planting is injuring the tap-root and rootlets by careless pulling of the young plant from the nursery, by rudely using the dibble, or by pressing the earth too firmly round the collar, and neglecting to do so with the roots. If a plant is carefully transplanted in damp weather, it should never shew any symptoms of the change.

Watering.—In dry seasons, artificial irrigation is of great use for giving due liquid aliment to plants, and is indispensable to those newly transplanted as above, in order to consolidate the roots. Watering, for whatever purpose, is most advantageously performed in the morning or evening. If done during the time the sun is shining, take care not to water the leaves of any plant. If the day be cloudy and cool, watering the tops of plants can do no harm. The watering, in any case, should resemble as nearly as possible a soft shower, and be performed with a rose watering-pot. The greater number of flowers are injured by watering, if the water touches their petals.

KITCHEN VEGETABLES.

The vegetables usually grown in kitchen-gardens belong to various natural orders, which, for convenience, we shall arrange in the following groups:—1. The cabbage tribe of vegetables; 2. The pea and bean kind; 3. Those grown for the sake of their roots and tubers; 4. The onion and leek kinds; 5. Salads; 6. Sweet herbs; and 7. Miscellaneous kinds. This grouping, it will be understood, has only a partial reference to botanical arrangement, and has been adopted in preference to the confusion of common alphabetic lists. For the technical classification of the plants here treated, the reader is referred to the sheets on SYSTEMATIC BOTANY.

The Cabbage Tribe.

The vegetables of this group belong to the order Cruciferæ, having cross-shaped flowers, and have, in fact, been all derived from the one plant, *Brassica oleracea*, which grows on the shores of the south of England. The garden varieties of this plant—cabbage, savoy, Brussels sprouts, cauliflower, and Scotch kale—all so unlike each other, and so unlike their indigenous prototype, present a series of the most remarkable instances known of the power of man to induce modifications in the size, form, and structure of an organic being, and to sustain permanently the races thus obtained.

Cabbage (*White*).—The cultivated varieties of the common or white-hearting cabbage are very numerous. The best varieties in ordinary use are—1. Small and large York; 2. London Market; 3. Sugar-loaf; 4. Knight's Downton; 5. Battersea; 6. Vanack; 7. Drumhead; 8. Sutton's Imperial; 9. Atkin's Matchless; 10. M'Ewen's; 11. King of the Cabbages. The cabbage is a biennial plant; it runs a two years' course, bears seed, and dies. To obtain hearted cabbages throughout the year, two or three sowings must be made; one in the spring, another in summer, and, finally, one in autumn. Spring-sowing can be effected at once, or it may be divided into two or three operations; because, from the third week of March to the first week of May, the seed can be successfully sown for the supply of summer and winter. Yet by attentive management, one sowing may be made to produce all that a family can require: we restrict our directions to that simple operation.

Prepare a bed of good sound loam in an open exposure, and let it be slightly manured. Dig the ground for four rows, nine inches asunder, and from fifteen to twenty feet long. Break the earth finely, and leave it to settle for three or four days; then place boards to tread on, while a first drill, one inch deep, is struck by the line; make the bottom of this and every other drill even, and a little solid, by patting it with the back of the rake. Sow the seeds rather thickly, because it is better to thin out an abundance of plants than to lose the greater part of a thin crop by insects. When sown, cover the drill with fine earth, proceed to make and sow other drills, till the bed be finished, and then either tread the surface over with the feet placed nearly close together, or pat the surface with the spade, and then finish it off smooth with the back of a rake. Always avoid to tread ground into holes, and therefore recede from the work backward; prefer to use the feet in light sandy soil, but rarely with stiff and binding ground. In a very dry season, seeds will not easily vegetate; therefore in such cases strike the drills, and water effectually along them for three successive evenings, covering the plot with mats throughout the day. In the third evening, make the drills even, sow, cover with earth, sprinkle again, and lay on the mats by day, till the plants be visible, then dust them once with the finest road-sand while the dew is on, and in the evening with air-slacked lime. These precautions need not be repeated. We never saw a set of cabbage, turnip, or celery plants so dusted with road-sand that was much infested with the turnip-beetle; and as to slugs, lime, or lime with coal-soot, will effectually prevent their ravages, or destroy the vermin.

When the plants begin to produce their true leaves, thin them out, first to an inch asunder, and again to two inches; they will thus gain strength rapidly; and when they have three or four good leaves four inches long, they will be fit to go out, some into nursery-beds, and others to the plots where they are to remain. Those set in the former, six inches asunder, will acquire stocky roots, and be prepared for successional beds. The size of the plants will indicate the season during any of the summer months. Those planted permanently will require the ground to be made rich with manure, and the transition from poor to rich earth will make them grow rapidly. The smaller Yorks, &c., should stand twelve or fifteen inches apart, the large varieties, twenty to thirty inches. Set each plant as deep as the base of the lower leaves, and observe the directions given for the treatment of broccoli. These seed and nursery beds will supply the table from May to November, and in fine seasons, even later.

Red Cabbage is only used for pickling; it is raised by a two years' course—that is, by sowing in August, and transplanting, as directed above. The heads form in the ensuing summer, and are in fine condition in October. If sown in spring, little-hearted cabbages can be obtained, which may supply a loss, or serve as a substitute for the others. The large or Dutch red is the best.

The Savoy is very hardy, and, like the cabbage, forms a close round head, but the wrinkling of the leaves serves to distinguish it. Its culture is very easy. Begin to sow in February; sow a second time in March; a third—and this is for the main crop—in April, about the middle of each month. Let the situation be open, the soil a good natural loam, if possible, and laid out in a bed three or four feet wide, digged, and made fine. Scatter the seeds evenly, and rake them. Repeat, for the fourth time, in August. The plants of this last sowing will attain a large size by the following August and September, if planted out in April. Moist weather should be chosen for planting, and the savoys should stand two feet apart. Keep the ground clean, stir it occasionally, and draw the earth towards the stems on each side, always, however, leaving a sort of furrow three or four inches wide, to receive the rain, and convey it to the roots.

Brussels sprouts produce tall stems, three or four feet high, which support a head somewhat resembling an open savoy, of little value. The lateral buds down the stem protrude a succession of little green heads, like small savoys, of delicate flavour. The following is transcribed from the *Domestic Gardener's Manual*, wherein the Brussels practice is noticed, and a few experimental remarks appended:—'The plants are raised from seed sown in March or April, of which an ounce may be requisite for a seed-bed of four feet by ten. Van Mons says: "The seed is sown in spring under a frame, to bring the plants forward; they are then transplanted into an open border with a good aspect. By thus beginning early, and sowing successively till late in the season, we contrive to supply ourselves in Belgium with this delicious vegetable fully ten months in the year; that is, from the end of July to the end of May. The plants need not be placed at more than eighteen inches each way, as the head does not spread wide, and the side-leaves drop off." In England, the Brussels sprout is so hardy, that it will stand twenty degrees of frost; and its head about Christmas is a tender and delicate kind of greens. Being then cut, the plant will remain nearly torpid till the advancing sun causes it to start into new vegetation; then the spaces between the rows should have a little leaf-soil or good manure, lightly forked in; and the young heads, all of which were quiescent, but visible in the winter, will speedily advance from the axils of the leaves, and yield a supply for many weeks, if they be properly pulled or cut off in succession.'

Scotch Kale and German Greens.—These are raised by sowing the seeds either in beds or single drills late in February, or early in March; to be first thinned out to three inches apart, and finally transplanted to beds or rows, wherein the plants are to stand thirty inches asunder. The plants may go out in succession from June to the middle of July. The heads are cut first, and subsequently side-shoots arise, which produce excellent winter greens till early cabbages come in. The plant runs to flower and seed during the succeeding summer.

Cauliflower, which is grown only for its rich white heads of metamorphosed flower-buds, which form one of the most delicate and highly appreciated products of the *culinarium*, requires a warm and moist climate. In Holland, it grows to great perfection.

Spring sowing, for a first crop, may be made in March, over a temperate hotbed. The seedlings are to be pricked out when the leaves are an inch broad; and from this nursery-bed they are moved to the garden-bed in May, to stand more than two feet asunder, the ground being made extremely rich. The plants, after they begin to grow, are occasionally watered with the liquid manure collected from the drainage of dunghills. A second spring-sowing is made in the open border in May, to obtain plants from September to November, by a similar mode of treatment. The last sowing occurs in the middle of August. The plants, when about four or five weeks old, are to be thinned out to two or three inches apart, the best to go into nursery-beds of rich earth, three or four inches asunder. Here they must grow till November, when the strongest are to be set out in rows, to be preserved under bell or hand glasses. Dig a bed of rich ground in an open situation, and make it still richer with manure; set three or four plants together, five inches apart, in patches, each patch a yard asunder; give water, and cover close with a handglass till the plants begin to grow. When fairly taken with the soil, tilt the glasses on the sunny side with a brick, and thus continue to give air on mild days during the winter, and on some occasions take the glasses quite off, but replace them, and cover close every night. In the spring, thin the plants to two under each glass, making good any deficiencies with some of the best

plants thus taken up, and plant the surplus in a warm spot of ground two feet apart. Keep the glasses on the other plants, raising them more and more, occasionally exposing them to mild rains till about the beginning of May—unless in the event of intense frost, such as we have experienced within a few years—when the glasses may be finally removed. Cauliflowers will thus be produced in succession throughout the summer.

Other plants should, in November, be placed in frames four inches apart, in a bed of rich dry loam, over a very slight hotbed: give water, close the lights, and be guided as respects the admission of air by the directions for the hand-glass division. The lights should be covered with mats and boards during severe frosty nights. In February, March, and April, the plants are removed in succession to beds richly prepared; and the cauliflowers will come into perfection during July and August. It is customary to form the earth immediately around the stems into the shape of basins, to contain water or the liquid manure: it is a useful practice, and this, with hoeings between the rows, will comprise the general treatment.

Cauliflower requires a very rich soil, and a warm situation. In many localities, especially in Scotland, it will be found impracticable to plant out in autumn; the plants must therefore be protected in frames until the spring.

Broccoli is one of the best vegetables of the cabbage kind, and is valuable for coming at a season when not liable to be affected by caterpillars. There are various kinds of broccoli, but all may be arranged under two heads—those for spring use, and those for use from September to Christmas; the latter are termed 'Cape' or autumn broccolies. The most approved varieties for spring use are Bowles's new sulphur, Moody's dwarf, Grange's cauliflower, and Portsmouth cream or buff coloured.

One ounce of seed of broccoli is calculated to sow a bed four feet wide by ten long, broadcast, on a prepared bed; but if sown in drills, rather less seed will be sufficient. Each kind should have a place allotted to itself. The soil should be a fresh and rich sandy loam, and the season for sowing will be comprised between April and July. The plants of the Cape kind are finally set out in beds made rather rich with manure, at any time when they have leaves a few inches long; two feet distances, plant from plant, will be sufficient. Each plant is to be firmly secured in the soil. This species will come in season in August, and continue to produce a supply throughout the autumn; in mild seasons, some heads may be cut even so late as the turn of the year.

The spring hardy varieties are treated by most persons in the same way as the Cape—that is, the plants, when they are six or eight inches high, are transplanted as they become ready, between the first week of July and that of September, into beds of richly manured loam, and set two feet apart, the largest sorts, as the Portsmouth, at thirty inches, and they are kept perfectly free from weeds. If the seasons be favourable, a successional supply of broccoli is thus obtained from the first week of March to the end of May. It is also customary to lay down plants in September, with the heads turned from the sun, applying earth on the south side over the stems, to protect them from snow and frost. We prefer to plant in six-inch-deep trenches, properly manured, removing the plants to them when not less than a foot high, filling each hole with water, and repeating the watering for two or more successive evenings. This treatment, even in the driest seasons, will secure the plants; and as the winter approaches, by drawing the earth from the ridges on each side, and thus filling up the trenches, the stems will be protected, and the ground levelled and rendered light. We have practised this method during seven or eight winters, and have lost no opportunity to recommend it to others. Broccoli plants do better in trenches than any other members of the Cabbage family.

To save seed, it is only necessary to watch the progress of some very fine plants left late in the spring, to cut out all the weakly and crowding parts of the heads when expanded, and to secure the seed before it be quite ripe, or rather, before it is shed by the seed-vessels. But as all these plants pass, by crossing or hybridising, into other varieties, it is generally not desirable to attempt seed-growing.

Instead of growing kale, cabbage, cauliflower, or any other of these plants from seed, it will save much trouble to the cultivator of a small garden to purchase young plants by the hundred from a market-gardener.

The Leguminous or Pea and Bean Tribe.

Of the Pea there are various sorts, but it is only those of a fine kind which are cultivated in gardens, and called *garden-peas*, that we require to notice here. When fresh, they are a bright green, and when dry for seed, most are a buff yellow, others of a bluish-green hue. Peas are a summer delicacy, and the chief art is to produce them in the open air, by the middle of May, and to keep up a succession of crops till other vegetables supersede them. Skilful gardeners do not consider it a difficult process to effect an early crop, as the plant is very hardy, and sustains violent transitions without much danger. Peas, therefore, may be accelerated in frames and vineries during February, and being transplanted into rows fronting a south wall, will continue to advance progressively though the weather be cold. They can also be sown—provided there be no frost—in the open ground at any time. There are many varieties of this vegetable, but we shall notice only those that have proved themselves worthy of general culture. The Early Frame, Double Blossom, Prince Albert, Early Warwick, and Bishop's Dwarf, are adapted for very early crops, but their produce is somewhat less than some of the following later kinds, which ought to be chosen for a full crop: Prussian Blue, Imperial, Knight's Marrowfats, Scimitar-podded, Fairbeard's Surprise and Champion of England. In the two varieties of sugar-pea—the tall and dwarf—the pod is destitute of the cartilaginous transparent lining usually seen in the pods of peas; this enables the pods to be used in the same way as kidney-beans.

The soil in which this vegetable most luxuriates is a free, light, but rich loam, abounding with vegetable matter, but not manured with recent dung. The situation for crops from June to August should be exposed and open. Some obtain an excellent yield from seed sown early in November, in long drills, in a sheltered situation; and if the winter be open, success is nearly certain. At whatever season persons commence, a better general rule cannot be adopted than to sow for a successional crop as soon as the peas of the preceding sowing are fairly above the surface. The plants, when three inches high, should have earth drawn against their stems on both sides; after which, the soil may be superficially opened by passing the hoe lightly through it, and thin branchy sticks, of a height suitable to the habit of the variety, ought to be thrust into the ground, converging a little so as to meet at top, and interlace each other. Shallow soils over chalk are soon over-cropped by peas, and refuse to bring a healthy plant; and in all kinds of ground, the frequent repetition of pea-sowing is to be deprecated. The land must also be purified by a rotation of cabbage and potatoes.

In country gardens, the field-mouse is a great enemy to peas, and where these are sown in winter or early spring, when food is scarce, the seed is sure to become a sacrifice to its ravages. Many methods have been recommended to obviate this mischief; but the most effectual plan, according to our experience, is to make a pretty deep furrow, and after depositing the seed peas in it, to cover them with small bits of chopped furze, after which, the whole is covered in with earth in the usual

manner. The furze being prickly, annoys the mice in their attempts to scrape up the peas, and they soon desist.

Stakes for peas are indispensable in keeping them from trailing on the ground; and therefore every person who wishes to grow this vegetable in his garden, should take care to preserve the stakes from one season to another, as long as they are serviceable. Any kind of branchy twig, such as those of the beech and the larch, will answer the purpose; and the better if they are open and spreading: they must be stripped of their foliage. When all the pods are taken, remove the haulm or pea-stalks to the compost dung-heap.

Beans.—These are planted in rows, and the seeds are generally sown at different periods between the 1st of May and the middle of July. The situation should be open, not crowded by other vegetable crops, or under trees—the soil, a free working loam, moderately manured. The drills should not be nearer to each other than thirty inches, and not more than two inches deep. In these the beans are to be dropped at regular distances, not exceeding three or four inches. Make the ground firm at bottom, but let the covering earth be light, and only slightly raked, not trodden or made hard. The one leading principle of successful growth, is to bring the plants up as soon as possible, and this is effected by selecting warm weather and well-prepared open soil. A cold, wet, cloddy condition of the land causes decay.

The kidney-bean comprises two species of plants, which, though of one family, are of very different habits. Both, however, are natives of the East, and are very impatient of cold; hence the necessity of deferring the sowings till the weather be nearly settled in the spring, and the ground warmed to the depth of several inches. The two species are, first, the dwarf, with its numerous varieties, all bearing the title of *French beans*—being forms of the *Phaseolus vulgaris* of botanists—and, secondly, that commonly termed *scarlet runners*, from the scarlet colour of the flowers, although there are varieties with white and variegated blossoms: this is the *Phaseolus multiflorus* of botanists. There are few of the many varieties of the dwarf which can surpass the buff or dun-coloured bean—it is free of growth, and fertile, either when forced in pots, or planted in the open ground. The black speckled dwarf is also an excellent bearer; the white-seeded is the true *haricot* of the French.

Runners are planted with similar precautions, or if sown early in pots and boxes, will transplant very well. When the plants attain the height of three or four inches, they should have a little earth drawn about the stem, and be staked; that is, somewhat tall branchy sticks should be placed on each side, converging towards each other at the top: these props ought to be eight feet high; and when the plants reach their summits, they should be nipped off and kept stopped, to cause them to produce fruit-bearing laterals. 'Gather beans, and have beans;' that is, never leave any pods to ripen; if redundant, let them be given away, or go to the pigsty, for a maturing pod arrests the fertility of the plant by tasking all its powers. Keep the crop clean, and the surface of the ground rather open. The roots of the members belonging to this section are accounted narcotic and poisonous.

The garden-bean is known to every one. Though a native of Egypt, it is, in all its cultivated varieties, very hardy. These varieties are numerous: some of the more approved are—the early *mazagan* for the first crops, which may be sown from October to February; early *long-pod*, an excellent fertile bean for general use, not highly flavoured; *broad Windsor*, the best of all beans for flavour; and the *fan-bean*, which produces an abundant crop.

Beans prefer a sound and rather firm loam, retentive of moisture. They suffer much in a very dry season and soil, particularly if attacked by the black 'green-fly' (*Aphis Rumicis*). But the attacks of this insect are not so severely felt by the gardener as by the farmer, for its hordes soon overrun whole fields, preying upon the juices of the plants, and thus preventing the development of the grain. In the autumn, when these flies take wing, they form extensive clouds in the atmosphere, and collect in sheltered situations to such an extent as to spread terror among the inhabitants: this is, in fact, the so-called 'cholera-fly.' *Topping*, when the insects are first seen, appears to be the only remedy. The seeds should always be sown in rows. Beans transplant well, and therefore may be sown thickly in autumn, covering the plants with hoops and mats, or with a garden-frame and lights.

When the plants rise in the rows, or begin to grow after being transplanted, loosen the earth by pushing the Dutch hoe along the surface, and draw three inches of it to each side of the stems; or rather, shovel up two or three inches of the earth, and lay it flat a foot wide on each side of the row of beans, shelving rather towards the stems than from them, for then the rains would find their way directly to the roots. The seasons of sowing are autumn for the mazagan, January and February for long-pods, and from March to June for the Windsor. Sow succession crops one after the other, according to the demand, as soon as the plants of the preceding sowing shall be quite above ground.

As the beans ripen and turn black, draw them up, and place them to dry in an airy situation, guarding the pods from mice, which are rather partial to the bean.

Lentil.—Within the last year or two, this crop has attracted some attention: it must not be supposed, however, that it is now brought into cultivation for the first time, for it wears the crown of hoar antiquity, in common with wheat and barley, and other staple products that have in all ages formed the leading food-plants of man and beast; it is, indeed, the oldest leguminous plant of which we have any record, its nourishing qualities having been appreciated at a very early period. For bread and pottage of lentils, Esau sold his birthright, and the plant is still in common use in Eastern lands, being parched in frying-pans, and commonly sold in the shops in Egypt and Syria. The following varieties have been introduced: 1. Large; 2. Common or yellow; 3. Red or small brown; 4. Common small. This crop requires a dry warm soil, and might be advantageously grown in arid sandy situations unsuitable for common garden crops. It is very impatient of wet. The manner of sowing is to plant a row of beans between each row of lentils, in order to prevent their falling upon the ground, and to avoid the trouble of propping, which, however, would be the more advantageous method. The lentils should be sown in pretty thick rows at 18 inches or 2 feet apart. One plant produces from 100 to 150 pods, each pod containing two or three seeds or 'lentils,' which are smaller than tares, and may be cooked in the manner of peas.

Root Vegetables.

The vegetables grown for the sake of their roots are of two kinds—1. Those in which the roots are more or less round or lumpy, including the Jerusalem artichoke, the potato, and the turnip; and 2. Those which are tap or taper rooted, including the carrot, the beet-root, the radish, and the horse-radish. Strictly speaking, the tubers of potatoes, &c., are not *roots*, but merely concentrated stems of the vegetable below ground, the real roots being small fibres which shoot out from the tubers, and bring nourishment to the whole. All require depth of soil to penetrate, and also looseness and breadth of mould to allow of expansion.

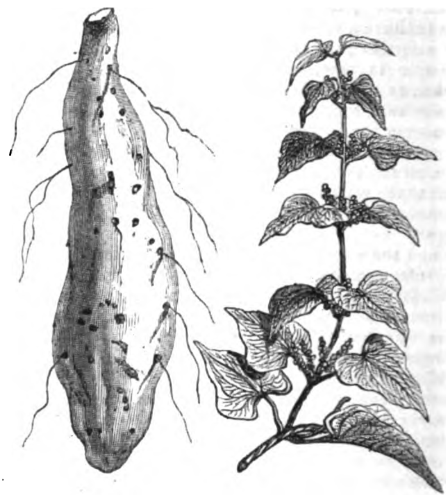
The Jerusalem Artichoke is a root which may be said to combine, in point of flavour, the turnip with the potato. Its name is an absurdity, for the plant has no resemblance to an artichoke; and the word *Jerusalem* is a corruption of the Italian name *Girasole*. The plant

is a native of Brazil, and botanically belongs to the same family as the sunflower, but it rarely produces flowers in the British Islands. The tubers, which alone are eaten, are produced abundantly under the surface, close to the base of the main stem. The plant is set like the potato, by either whole roots or cuts with one or more eyes to each. The pieces or cuts should be prepared at the time of planting, and set by depositing in shallow trenches two feet apart, and one foot asunder in the row; and being covered with earth, nothing more will be required but to keep the ground clean by the hoe. The season for planting is in the first dry weather of March; and half a peck of tubers, according to Abercrombie, will plant a row 120 feet long. A good mellow loam is the proper soil, and the spot for planting should be apart from the vegetable-garden, otherwise this prolific plant may intrude, and become a complete nuisance. Being set in March, the plant is perfected about October or November. Dig only when wanted, if that be convenient; but if there be a danger of frost, as will most likely be the case, lift the crop, and store away for winter use in moist sand or any kind of light soil through which the frost cannot penetrate. This excellent vegetable is but imperfectly appreciated in Scotland, and even in England.

The potato, like the Jerusalem artichoke and some other plants, is a naturalised exotic in English gardens from the wilds of America, and has been greatly improved by culture within the last hundred years. There are many varieties, individually distinguished by colour and flavour; and as some are better than others, it is very important that proper sorts should alone be cultivated. There are two distinct kinds—*early* and *late*. Early potatoes soon come to perfection, and cannot be stored for future use. On this account, as well as on account of the small amount of produce, they are rather grown as a luxury than as an important article of food for the cottager. The true potato is the late kind, which will store for winter and spring use. Of this there are hundreds of sorts, every district apparently having one which is best adapted to its soil and climate.

The potato may be cultivated either from seed procured from the apple on the stalk, or from the tuber itself. If from the seed, the first crops of tubers are only a little larger than peas, and several seasons are required to bring the plant to an edible size. The common method of cultivation is by pieces or cuts of the tuber, each having at least one well-defined eye; cuts with two eyes are generally preferred. These are set in trenches, the ground being in good heart with previous manuring, or good old manure placed in the bottom of the furrow along with the sets. The season for planting is late in April. Dig and plant sets, fresh cut as the work proceeds, placing the sets from nine to twelve inches apart, and the rows being about twenty inches asunder. Heap six inches of soil loosely over the sets, and when the shoots have risen sufficiently above ground, keep earthing them up with a hoe. When the stalks begin to decay in October, the crop is ready for lifting. Constant stirring of the soil, and earthing up, is the great point in potato culture. (For further information on potato culture, see AGRICULTURE.)

The Chinese Potato.—Under this name has recently been brought into notice a crop which may erelong acquire some importance, although the promises held out of its forming a complete substitute for the precarious potato crop are not likely to be fully realised. The new plant, like the East and West Indian yams, previously known, belongs to the genus Dioscorea (*D. Japonica* vel *D. Batatas*), and has been cultivated with sufficient success in Britain to shew its suitability to our climate. In China, it has been long known. The adjoining drawing shews the foliage and root of this plant; the latter is very long, and therefore requires a deep light soil. The French horticulturists believe that in point of flavour and nutritive properties, it is equal to the potato; that the yield is greater, whilst freedom from disease renders the crop more certain; that it will grow



Chinese Potato (*Dioscorea Japonica*).

upon sandy and poor soils; that it can be propagated with facility; that it may remain in the ground several years not only without degenerating, but, on the contrary, increasing in size, weight, and nutriment, 'furnishing at all seasons of the year an aliment within the reach of every one;' that when harvested, it may be preserved in cellars or sheds, without vegetating, for many months after the potato has become useless for food; and that it requires a shorter time in cooking than the potato, ten minutes boiling being sufficient. Our observations of the culture of this crop in Scotland during the two past seasons—1855 and 1856—lead to the conclusion that these advantages will not be so fully realised in northern countries as in the south of France; but the crop appears well worthy of continued attention as a valuable addition to our culinary plants. The system of cultivation, based on Dr Lindley's recommendations, is as follows: The smallest tubers are set apart for propagation, and pitted to guard against frost. In spring, they are planted in furrows, in well-prepared deeply dug ground in a warm situation; the young shoots soon appear, and may be made available for cuttings, if there is a scarcity of roots. The ground should be kept quite free from weeds by stirring of the soil, &c., during summer, so as to give the plants free exposure to the sun and air.

Of the Turnip there are many varieties; the leading ones grown in gardens are—the *early Dutch*, which is white; the *yellow Dutch; golden stone;* the *Swede; orange jelly;* and the *black turnip.* The white is the most delicate while young, but the yellow Swede is preferable as a keeping or late turnip. The yellow Dutch has also an excellent flavour. Turnips are cultivated from seed in drills one foot or more apart, and thinned when they come into leaf, to afford room for their expansion. For the two Dutch varieties, the best soil is sandy, enriched with bone-dust, guano, or good old stable-dung. Small sowings should be made in succession from March till July, and then the main crop for winter should be sown. Swedes should be sown in April and May. Deeply hoe the ridges after thinning, and keep the surface clear of weeds.

Of the Carrot, the favourite varieties are the *early horn*, the *Altringham*, and the *white Belgian.* All require a deep light soil. The early horn is sown in February for the spring crop; the other kinds are

sown in March, April, and May. All are sown broadcast in beds, and on a calm day, if possible, as the seeds are very light; they should also be rubbed between the hands, and mixed with some dry sand or wood-ashes, to separate them, and so facilitate an equable sowing. The seed may be saved by planting a few of the best carrots to stand the winter; seed will not retain its growing principle above a year, and therefore requires to be purchased with caution. Carrots may be stored like potatoes in winter; and it adds materially to their preservation in a sound and sweet condition, to riddle over the layers a few barrowfuls of dry mould or sand. The Altringham is best suited for a full garden crop; but all the varieties are in many soils subject to insect attacks.

The Parsnip is a taper-rooted vegetable, resembling the carrot in shape, and in England is a delicious vegetable. It is an excellent agricultural as well as horticultural crop, being extensively grown for cattle on the continent. It requires a rich deep soil, trenched and manured as if for a crop of carrots. The seed is sown in drills a foot asunder. The period of sowing is comprised between the last week of February and the first week of May. On thinning out, let the remaining plants be nine inches apart in the row. Parsnips are not liable, like carrots, to be injured by severe weather; but if taken up before Christmas, and properly protected, they will continue good till May in the following spring.

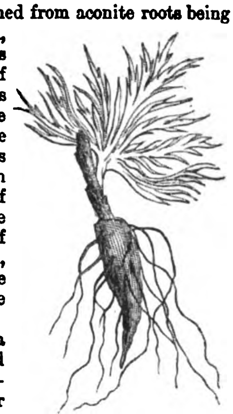
Of the Radish there are numerous varieties generally cultivated. According to Lindley's catalogue, these are— 1. The long white; 2. Purple or salad radish; 3. Salmon or rose-coloured; 4. Scarlet; 5. White Russian radish; 6. Crimson turnip-rooted; 7. Early white; 8. Purple turnip; 9. White turnip; 10. Yellow turnip; 11. Black Spanish; 12. Brown oblong; 13. Large purple; 14. Round brown; 15. White Spanish, a large bulb, which in good soil grows to the size of a small stubble turnip.

Numbers 2 and 3 are the best of the spindle-rooted radishes; numbers 6 and 7 of the early turnip-rooted. The winter black radishes are rarely seen in gardens; but the large white (15) is very mild, if the soil and season be favourable, and its texture is tender.

Sown in February and March, the spring radishes come into use in April and May; if required earlier, they must be protected by frames or mats. The market-gardeners obtain them early by gentle forcing, covering the beds every severe night. The sowings of all the early varieties may be repeated monthly till August. The winter radishes are sown in July and August, and come into use from September till the spring. A rich and light soil suits the radish, with occasional copious supplies of water; and rapidity of growth is required, otherwise the roots will not be tender, nor will the flavour be mild.

Spottiswoode's Rat-tail Radish.—In 1856, a remarkable kind of radish was raised in the Edinburgh Botanic Garden from seeds sent from India by Mrs Colonel Spottiswoode. It is called the Rat-tail Radish, and the edible part or 'radish' is not the root, but the seed-pod in a green state; when sown early, it produces a very abundant crop, and is well suited to the climate of Britain. The young plants require to be thinned out to a foot or more apart, in rows of about two feet, and plentifully supplied with water during dry weather. The radishes or pods of this plant are very delicate, and well adapted for salad.

Horse-radish is a plant which in most soils is of uncontrollably luxuriant growth: it is a most pernicious weed where it intrudes, on account of the multitude of vital germs with which its root-stock abounds, and by which it is rendered a sort of vegetative polypus, every inch of it being capable of developing a growing bud. The horse-radish is thus of very easy culture, but to be grown to perfection, requires a deep soil. It is ordinarily grown in an out-of-way shaded corner, and left without care, furnishing in this way an ample supply of roots. Serious accidents have happened from aconite roots being used instead of horse-radish, and therefore great caution is required. With the view of supplying instruction on this point, and preventing future accidents, specimens of the two roots have of late years been placed side by side in the botanical museums of Kew and Edinburgh, and we here represent the root of the poisonous aconite, which, it will be seen, is quite different from that of the horse-radish.



Root of Aconite, a poisonous plant, occasionally mistaken for horse-radish.

Beet-root.—The plant is a biennial; that is, it grows and perfects its roots in one season; in the following summer it sends up its flower-stalk, ripens its seeds, and dies. Of the two varieties of red beet, the smaller deep-purple variety is greatly preferable to the larger, which approaches to, and is little better than, mangel-wurzel. We select two varieties: 1. The short-rooted deep-purple beet, for its root; 2. The *Beta cycla*, or silver beet, the leaves of which only are used in lieu of spinach.

To grow the red beet well, the ground ought to be light and pulverisable, otherwise the spindle-root will be diverted if it meet with obstacles, and become forked and distorted. Trench the plot to the depth of eighteen inches, removing large stones, roots, and hard clods of earth; lay a stratum of manure at the bottom of the trench, in order to attract the root downward; then return the fine earth. Let the work be completed before frosts set in, and mark out the beds according to the number of rows required. At the middle or latter end of March, the seeds are to be sown. In sowing, stretch the line, and draw an even drill about an inch or an inch and a half deep, and drop the seed-vessels at even distances, two or three inches asunder; for although these spaces are much too small for final growth, it is in all cases wise to be liberal of seed, because insects and other enemies destroy many plants, and thus a season may be lost. Cover with light fine earth, and tread or beat the covering earth with the spade. If the plants rise equally, thin them gradually, till they stand from nine to twelve inches apart every way, or even eighteen inches for the large-rooted variety. Beet will transplant, but the operation dwarfs the plants; and at best it is attended with some risk. Keep the rows or beds entirely free from weeds by hand-weeding or flat-hoeing. Some roots will be ready in September, and thence throughout winter. In using them, or prior to storing up during winter, cut off the straggling leaves, being careful not to wound the roots; they keep well in dry and well-washed sand, but become tainted if wet straw or decomposable vegetable substances are present.

The Onion Tribe.

This savoury class of kitchen vegetables comprises the onion, leek, garlic, and shallot, the two former being by far the most important. All are natives of Eastern countries; but they grow to great perfection, as respects pungency of flavour, in the British Islands.

The Onion.—For a crop of onions, the soil should be rich, light, and deep, and well exposed to the sun. Before sowing, work and enrich the bed to the depth of eighteen inches, and then beat it flat and firm with a spade. Sow the seeds broadcast, at any time in March, or even so late as the beginning of April. Sift fine sandy earth over the seeds, and pat the surface even. As the onions advance, thin them out according to the variety. Keep the ground quite free from weeds. In September,

twist the necks, take up the crop when the leaves become yellow, and expose the onions to sun and air under a shed till they be externally quite dry. Many sow onions in drills, but space is lost by that method.

A summer supply of onions, at a time when the previous stock is exhausted, and the growing autumn crop has not come into season, must be desirable, and it is said to be easily obtained. Prepare the ground early in February; select a number of those small bulbs that are always found in every bed of the larger kinds, which are not above an inch broad. The bed being ready about the end of the first week, mark out squares on the surface by means of cross-strings, but do not move the ground. At each intersection of the lines, press in an onion, the root downward, to one-third of its depth, so that the bulb may remain firm and erect. Thus, when completed, the bed will exhibit the onions in squares five or six inches asunder. The onion forms its bulb in the first year of its growth, and the flower and seed in the second year. These small onions will therefore naturally attempt to produce a flower-head, which, as soon as it is fairly visible, is to be pinched off. Another attempt will be made, and that also must be frustrated. The natural course of the vital fructifying sap being thus interrupted, will be diverted to the bulb, and gradually, almost imperceptibly, two, three, or four onions of medium size will be produced and grow freely. These are to be taken, as soon as they are ripe—which, if the summer be fine and sunny, with occasional showers, will be in July—and dried in the open air as before directed.

The potato-onion is very valuable on account of the heavy crop it produces in this way. The tree-onion is also no less useful than curious.

The Leek, if properly treated in a favourable soil and situation, grows to a very large size. It is a plant which is much improved by proper transplantation, but yet can be grown very well in its seed-bed. The Musselburgh leek is the best. Sow the seeds in a shallow drill at the close of February or early in March, and cover them with half an inch of fine soil; as the plants grow, keep the surface clear of weeds by hand-picking and passing the Dutch hoe lightly on each side of the leeks. Presuming that they are thinned out at first to stand three inches asunder, half of the plants will remain, and the other half will be removed to another situation. Thus the plants in the seed-bed will stand six inches asunder, and will be greatly assisted if the ground be opened on each side of them at the distance of nine inches, and manured spit-deep. A crop of fine middle-sized leeks will thus be obtained in the succeeding autumn.

To transplant leeks, prepare a bed at the end of June, to contain either two or four rows, nine inches asunder, and manure the soil richly to the depth of a foot or fifteen inches. Let the bed settle during a week or more, and in July make holes along the intended lines six inches deep and as far apart. Collect a number of the strongest leeks, trim off the straggling roots, and all the suckers or offsets. Drop a small handful of powdery manure, or reduced year-old cow-dung, into each hole, place in it a leek, and holding it by one hand, fill the hole with water. The object is to fix the leek as in a case, to which it can adapt itself, and will fully occupy, becoming, under propitious circumstances, a plant of large size and of most excellent quality.

Garlic, one of the most pungent species of *Allium*, is increased by dividing the bulbs into cloves or smaller bulbs, and planting them in good sandy loam at any period between the middle of February and the end of April. Draw drills two inches deep, and ten inches apart, then press the root-end of each clove firmly into the earth till it stand erect; let the distance between each be six inches, and fill up the drills with fine sand. Keep the ground free from weeds, and when the leaves turn yellow—which usually happens about the end of July or the beginning of August—take up the bulbs with a trowel or handfork, and keep them in a dry room.

The Shallot is a native of Palestine; its culture is precisely the same as that of garlic, therefore both may be grown to great advantage by adopting the plan suggested by the late Mr Knight (*Trans. Lond. Hort. Soc.* ii.). Let a rich soil be placed beneath the roots, and raise the mould on each side to support them till they become firmly rooted. This is then removed by a hoe, and by pouring water from the rose of a watering-pot, till the bulb stand wholly out of the ground. Thus they become mere surface bulbs, supported entirely by the fibrous roots, which pass deeply beneath into the rich soil. The growth of these plants, Mr Knight adds, so closely resembled that of the onion, as not readily to be distinguished from it till the irregularity of form became conspicuous. 'The form of the bulbs, however, remained permanently different from all I had ever seen of the same species, being much more broad and less long; and the crop was so much better in quality, as well as more abundant, that I can confidently recommend the mode of culture to every gardener.' Shallots have a strong but not unpleasant odour, and are therefore generally preferred to the onion for various purposes of cookery, and for making high-flavoured soups and gravies.

Chives, one of the smallest of the garlic tribe, is a hardy and useful vegetable, far superior to young immature onions. The plant grows in tufts somewhat like small rushes in appearance, but of a colour resembling the yellow green of young onions; it never bulbs. A crop is readily increased by dividing the roots in April or early in May.

Salads.

Salads are those plants whose fresh leaves are eaten at table raw, or only dressed with zests and condiments without the preparation of cooking. The principal vegetable of this kind is

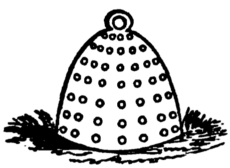
The Lettuce, of which there are several varieties, but all may be classed under two heads—the upright or cos lettuce, and the cabbage-lettuce. In spring culture, sow every month in very shallow drills of fresh-digged ground, in good heart, made rich with rotten manure. Strike the drills a foot asunder, and as the plants rise, thin them to stand in regular order, first to two inches, then, for table use as small salad, to six inches, and for the larger sorts, finally to one foot. With care they may, in moist weather, be safely transplanted during spring and summer. Spring and summer lettuces are sown from February to July. In September, two small sowings should be made of the hardy sorts, to come into use during late winter and spring; but it would be safer to make use of a large three-light frame. Some lettuces heart freely; those which do not, should be assisted by passing a string of bast round them from the middle upwards. This bandage must not remain many days, otherwise the plant will run to seed, and become bitter.

In autumn culture, sow in August, in drills pretty close together, for the express purpose of transplantation in September or October; they will not then run up. When the plants are three inches high, thin out half of them, and transplant some into warm quarters, and others under a frame; protect by coverings of hoop and mats those in the open ground; and if they bear the winter, thin the plants early in the spring to six inches apart. The plants in the frame will rarely fail if the earth be free from slugs.

Endive is a salad of a pleasant bitter taste. There are three principal sorts in ordinary cultivation—the *green-curled*, *white-curled*, and *Batavian*, with undivided flat leaves. The seeds are sown at different periods between the beginning of June and the second week of August, as required for the autumnal, winter, and spring crops. When the plants are three or four inches high, they may be removed to beds of moderately enriched

loam, to stand a foot apart. But transplantation is not essential, for very fine plants are produced in the seed-beds. When they are nearly full grown, they must be prepared for the table by blanching, as otherwise they would be too bitter for use.

Blanching may be effected by several methods: the most simple is that of passing a string of soft bast matting round the leaves of each plant, so as to exclude the light from the heart; but as hard frost is very injurious, some plants ought to be removed to a bed of dryish earth or sand under an airy shed; or a garden frame, partially covered, might be placed over a certain number of those already tied up. A good kind of pot for blanching is one of French invention, made of earthenware, and perforated with holes, as represented in the adjoining figure. Many persons blanch by only throwing straw loosely over the plants, but this makes a litter not very pleasing in a garden. The curled endives would blanch in a short time without tying within a darkened frame or pot, and be thus less liable to decay; for it is known that the plants suffer from being tied. The Batavian endive, however, requires a bandage at all times, otherwise its harsh green leaves will be useless, and the central heart, which alone is edible, will never be rendered tender and white. Some persons blanch in a simple way by laying a tile over the open heart of the vegetable.



Garden-cress.—In alluding to the culture of this common salad, we will include *mustard*, because they naturally are companions, and are often grown together. In cultivating mustard and cress, it is essential only to remark, that the latter should be sown three or four days in advance of the former, because cress is more tardy than mustard. Both are very accommodating herbs, inasmuch as they will grow upon wetted flannel in a saucer placed in any apartment, as well as on the floor of a green-house. On shipboard, under cover, they can thus be obtained throughout the winter; and in the garden from March to November, by successional sowings made once every fortnight. Sow either broadcast over the surface of a fresh-digged bed, raking and patting in the seeds by the flat of the spade, or in shallow drills half an inch deep, covering the seeds with a little fine soil. Sow thickly; and if the young plants rise, as they are apt to do, with a covering or cake of earth over them, remove it by means of a light heath-whisk. This salad should be taken before the true rough leaves be fully developed, a precaution which is often neglected in Scotch gardens, hence the want of appreciation of this salad.

Water-cress, a native plant, is grown to most advantage by the edge of running streams.

Celery is a native of Britain, found in ditches and marshes near the sea. The odour of the wild plant is very rank and disagreeable, and its juice is acrid and dangerous. By cultivation, this dangerous weed has been brought to the condition of that highly esteemed vegetable which is called sweet-celery. Of this there are many varieties—the common upright hollow white celery; the purple-stalked; the giant white and red; solid; Goodall's white, &c. Celery may be sown in a frame, with gentle heat, at the end of February, for the first crop, and thence to the end of May, on a warm sheltered border for succession. All the seedling plants should be pricked out into intermediate beds of soft rich earth—the first sowings over a gentle hotbed—to bring strong transplants in June and July.

The roots of celery become bushy, and its leaf-stalk firm and stout; it likes moisture, and the soil to be rich with decomposed vegetable matter. Self-sown seed, that which falls from a seedling plant, if it light on rich earth, as that of a newly dressed asparagus-bed, in October, will bring noble plants in the spring, fit to go at once into trenches. If produced by autumn-sown seed, nothing more is required; but the spring-sowings will always furnish weak and lax plants, that, when grown three inches high, must be removed to a nursery-bed over manure to strengthen and become stocky. Few kitchen-gardeners can obtain these plants till June, unless grown constantly under glass.

To trench for celery, prepare the trenches by previously manuring the whole plot; and after the ground has settled, dig a trench or two for the first plants a moderate spade's depth, depositing the earth on a ridge to the right and left of the trench. Clear the bottom, lay on it three inches of leafy manure, and re-dig the ground, to incorporate it with the manure. Then select a number of the strongest and most regular plants, trim off loose straggling fibres, and all the side-suckers, but do not touch a true leaf: set the plants four or five inches, and the large sorts six inches, asunder, and fill the holes with water; shade during sunshine for three days, and give water every evening, unless there be copious showers. The size of the young plants will indicate the season for transplanting.

As to future attention, water the plants frequently in the evenings till they begin to grow; and when they become three inches higher, stretch a line along each edge of the trench, and cut down by the spade as much soil as will suffice to earth the stems to that height; break it fine, and grasping each plant firmly in the left hand, insinuate the soft soil around it; then place a little finely reduced manure along the channel of the trench on each side, remote from the stems; this will nourish the fibres, without coming into contact with the leaves; water poured once or twice along the course of this manure will promote its action. Repeat the earthings as often as the plants advance three inches, and manure the extreme edges where the spade has made a groove, till at length the trenches become level with the surface of the ground. Then dig out soil, and add it, sloping ridgewise, till the plants are 'landed' up fifteen, eighteen, or more inches above the surface level. Celery may be preserved from frost by boards placed as a pent-house over the leaves.

Celeriac, or turnip-rooted celery, is raised and nursed in the same way as celery; but in planting out, the ground is dug and enriched, not trenched, and the plants are set by the dibble or garden trowel along the course of shallow drills drawn by the hoe, six inches apart, watering them freely. As the growth advances, bring earth to the plants, by which the knobby roots will be blanched, and made delicate and tender. When these are the size of small turnips, they are fit for the table. Celeriac is never eaten raw as common celery, but is boiled, and served up with melted butter. The seeds of both the species ripen freely in the summer of the second year, and many fine plants are obtained from self-sown seeds, which may serve as excellent substitutes should the spring-sowings fail.

Sweet Herbs.

Rosemary and *Lavender* are hardy undershrubs, natives of the south of Europe. They yield powerful essential oils when distilled with water, that of lavender being employed, as are also the dried flowers, in the preparation of the spirit called *lavender-water*. Bees are extremely partial to the flowers of rosemary. Both these plants are propagated with great facility by slips of the young side-shoots, trimmed of the strip of ragged bark, and merely dibbled into the soil. They will grow almost anywhere, and in any aspect; but the flowers possess the highest degree of fragrance when the plants grow in a dry, sandy, or gravelly earth. Spring or September is most favourable for propagation by slips.

Thyme and *Lemon-thyme* are used in seasonings; the latter is one of the most fragrant herbs of the garden; both are raised from seeds sown early in spring, or by

opening the earth around the stems, spreading the reclining shoots like layers upon it, and strewing some fresh sandy mould over them. Roots are soon formed, and thus a supply of young plants is obtained. It appears essential to renew thyme, and to place it—lemon-thyme particularly—in new soil, otherwise the plant dwindles and perishes. A dry and rather poor soil seems most favourable to the growth and fragrance of thyme, which may be economically grown as a border.

Sage, red and green, is propagated in the same way as lavender.

Of Marjoram there are three sorts—*pot marjoram*, *sweet* or *knotted marjoram*, and *winter marjoram*—all hardy or sub-hardy perennial and biennial small shrubs, natives of the south of Europe, which grow readily in a dry light soil, but require change of situation. The first and third sorts may be propagated by division, in the manner of thyme, but the sweet marjoram should be raised from seeds sown in April every year, the plants to be thinned out to the distance of six inches. The flowers are gathered usually in July.

Savory.—Winter and summer savory; the former is propagated either by slips and cuttings, by separating the lower shoots, or rooted offsets, in spring; the latter is an annual, sown in April, and becoming fit for gathering in the summer and autumn.

Mint.—Spear or garden mint, and peppermint, are not properly sweet herbs; the latter, indeed, is only used medicinally, the essential oil possessing pungent qualities. Spear, or garden mint, is used in the kitchen for a variety of purposes familiarly known. All the species, including *pennyroyal*, another medicinal mint, are cultivated by division of the roots in spring. Mint delights in moisture, and extends with great rapidity. Care, however, is required to give it a new situation when the plant becomes weak, and its leaves appear of a pale and yellowish hue.

To dry and preserve these herbs, select the shoots just as the flowers form and shew colour, but before they expand; suspend them in an airy situation, under cover, not exposed to the sun.

Miscellaneous Vegetables.

Artichoke, though esteemed by many, yet is found in few gardens; it is a native of the south of Europe, and was brought to England nearly three hundred years ago. Two varieties of it are cultivated in the best gardens. The plant has fibrous, rather fleshy roots, large deeply cut leaves, whitish with down, and it produces an upright stem, bearing at the summit an oval or roundish flower-head, not unlike a thistle. Artichokes can be raised from seed, but much more speedily by offset-suckers, which are produced freely by the parent plant. Select a spot of open ground; any soil will do, but a free light loam is to be preferred. Dig out a trench two feet wide, and of the same depth, if the good soil extend so low; if not—and this remark will apply to every future allusion to trenching—remove all the good soil, whatever its depth, to a space beyond the boundary of the furthest intended trench, and dig and turn the inferior bottom soil, incorporating with it three or four inches of good half-decayed stable manure. Then mark out another two-feet trench, and throw into the first, eight or nine inches of the surface-soil of the second trench; add another similar layer of dung, and work it and the earth thoroughly together. Again, throw in the remainder of the good soil of trench 2, and add a third layer of manure, which mix also with the soil. Thus trench 1 will be completed; and by repeating the work till the earth dug out of 1 be deposited in the last-intended trench, all will be manured and laboured alike; and a piece of rich ground will be prepared that may be expected to keep in heart during many years. The work ought to be performed before frost sets in; and if the land be heavy, it will be prudent to set it up in ridges.

Suckers are generally ready in April; and gardeners are willing enough to part with them. Having procured the desired number, level the ground, dig a portion of it again, and reduce the surface to the finest condition possible; then, after trimming off decayed leaves and damaged roots, plant the suckers in a row, two feet asunder. It is usual to form a complete bed of three or more rows, five feet apart—and we have prepared ground, as above, for such a bed—but some think that artichokes and other permanent vegetables ought to be set in single rows ten feet apart, because the ground between the rows can be cropped with other annual vegetables, which will benefit the artichoke, by the rich manure applied at the first and other successional croppings. The garden, in all its crops, permanent or temporary, ought to be made a laboratory of corrective rotations, wherein one crop shall attract and consume that which has been left by another. A dozen good artichokes will be sufficient for a moderate family; but as some suckers may fail, it will be prudent to set the plants one foot asunder, securing the roots firmly in the soil, and giving a copious watering at the time of planting, the supernumeraries can be removed when all are safe.

The subsequent culture is as follows: Hoe occasionally to destroy weeds, and keep the surface open. A crop cannot be anticipated during the first year; and if little heads be pushed up, it will be wise to remove them as soon as seen. When the plants become torpid and yellow in autumn, a few of the outside leaves are to be scaled off by the hand; the ground should then be marked by the line on each side at eighteen inches' distance from the plants; and being cut straight by driving the spade to its full depth along the line, the earth is to be dug up, broken fine, and laid on the surface of the eighteen inches left on each side of the plants, bringing it carefully against them, so as not to fall into their hearts, but yet to protect them effectually near the tops of the leaves; the operation is called *landing up*. This done, fill the trenches with stable litter, straw, dung, or fern; and in the event of hard frost, bring more litter close to the plants, and lay it over the *landing* earth, for artichokes are rather tender, and may be destroyed during severe winters. This practice is to be observed every year, with the additional precaution to cut the flower-stems close down.

Spring-dressing consists in removing suckers after levelling the earth, and digging in a little of the short manure that is left on the ground after clearing away the straw, &c., and making the soil neat. One or two of the strongest suckers may be left on the stock.

Asparagus is justly esteemed one of the choicest vegetables of the garden; and indeed it possesses every quality to recommend it—flavour for the palate, hardihood of constitution, facility of culture, and it brings profit to the grower. It is a native of the British Isles, but in its wild state bears little resemblance to the plant in a state of cultivation. Perfectly hardy, so much so as to resist a frost below zero, it nevertheless benefits by protection and generous tillage. In forming new plantations, it is customary to purchase two-years' old plants, because they are safely removed at that age, and will come into bearing in two years more. April is the best season for planting; but having ourselves produced beds from *seeds*, we prefer that method of propagation. Let the ground be prepared before frost sets in by deep trenching and rich manuring; but by all means adopt the practice recommended by Grayson, who produced what he styled *giant asparagus* about the year 1830. We give his own concise directions in the following quotation: 'If your ground be stiff and unpleasant to work, get some milder earth to mix with it, and a very large cart-load of rotten dung to about every ten square feet; trench it two spit deep, and loosen the bottom; let the dung and earth be well mixed together. When your land is fit for planting, draw your drills six inches deep, and sixteen inches from the first row to the second; that will form

a bed; and ten inches between each plant in the row. Do not raise your beds till they have been planted one year; then put on about four inches of mould out of the alleys, and cut till the 10th of May. If you keep them well manured, they will last twenty years; but *never cut later than the 4th of June.* Let them be eight feet in the clear from bed to bed, so that you may crop between, and lose no land.'

Here we find the sum of all that constitutes asparagus planting; but after all, persons must be content with such plants as the constitution of their ground will produce: for this very sort, which in the rich alluvium of the Thames produces shoots an inch in diameter, dwindles in the loams of ordinary gardens to less than half that size. Nevertheless, if the beds be narrow, thoroughly manured at first, remote from each other; if, also, about February of the first year after planting, a trench, eighteen inches deep and a foot wide, be formed on each side of the narrow bed, and twelve inches distant from the plants, and be half filled with the best rotten dung, incorporated with an equal quantity of the earth dug out; a most excellent asparagus will be obtained speedily, and the quality will not deteriorate. This enrichment may be occasionally renewed, but these auxiliary trenches are to be made at an increased distance each time, so as to avoid cutting and mutilating the roots, which extend very rapidly. Saline applications prove of great benefit to asparagus.

The seed of asparagus may be purchased, but it is yielded abundantly by every good bed, and should be gathered before it falls off, and kept in the berry till spring. We will presume the object to be double—first, to raise bearing-beds; and, second, to raise a stock of young plants for forcing. In the former case, the ground is to be in readiness for narrow beds, eight feet asunder; in the latter, wide beds, like those directed for artichokes, should be made. Towards the latter end of March, rub out the seed, and place the line along the course of the bed; strike two drills with the hoe at the distances directed by Grayson, two inches deep; or in the broad beds make similar drills nine inches asunder; and in both scatter the seeds pretty thickly, say half an inch apart; cover with fine earth, and pat it to a smooth surface with the spade. Watch the coming up of the plants, and be prepared to dust them with air-slaked lime, if slugs threaten them. When they shall have fairly formed rows of young seedlings six inches high, thin out the *narrow beds* first to four inches apart, and again to nine inches. The *seed-rows* for forcing, thin first to three, and afterwards to five inches, and then leave both to grow, observing to use the hoe repeatedly to keep down weeds.

In future treatment, when the stems become yellow, cut them down at two inches above the soil; clear the surface with hoe and rake, and lay on the beds eight inches of decayed leaves. This surface-manuring, which will generally take place about the end of October, will tend greatly to protect the young plants, and impart a stimulating principle to the ground; so that in early spring the plants will be strongly excited, and rise through the remaining manure in perfect safety. The trench-manuring, also, before alluded to, will come in aid of the top-dressing. We have cut excellent 'grass' within three full years of the sowing, and still reap profitable crops from beds twelve years old. These annual enrichments, be it observed, might be persisted in with every bed that is used for cutting; but for the beds devoted to raising plants for forcing, it will suffice to make the ground thoroughly rich at the time of trenching; because the plants, when three or four years old, will be removed to the forcing department; yet a coating of half-decayed leaves or manure, after the stalks are cleared off, will not be lost, as the stronger the plants, the more remunerative will be the produce.

When once asparagus is in full bearing, if the cuttings be judiciously made—that is, by taking only the strong shoots, always leaving one or two of medium strength to each crown, and duly applying manure—a bed may keep in high condition for twenty years. But it must not be forgotten that if every shoot be taken off a crown, to the end of a long season, that root will be destroyed. To prevent the crowns from being too deeply buried, in consequence of the autumnal dressings, it is customary to fork the beds late in March, digging them carefully, or rather loosening the surface with a fork of three prongs, and raking the rough earth into the alleys; this operation also gives freedom to the plant by opening the soil.

With respect to forcing, it is very easy with narrow distant beds to bring the plants somewhat more forward in the spring, by digging trenches eighteen inches wide, or wider, and above a foot deep, and filling them with warm stable-dung, blended with a third part of forest-tree leaves, raising the dung to six inches above the surface-level. The gentle warmth communicated will stimulate vegetation, and it would be assisted by covering the beds with hoops and mats, or with boards set up ridgewise, in the event of sharp frosty nights. Successional forcing-beds are prepared as soon as the cutting of the earlier begins to decline, or even when it is at its height.

The Cucumber and *Melon* are somewhat delicate in growth, and require a fine climate and extremely rich soil. The cucumber is usually grown over a heap of old horse-dung, on a spot of ground open to the south, and large enough to permit a two or three light frame to rest upon it. Dig out the soil a foot in depth, and lay it on one side, or around the trench. If this soil be a light friable loam, incorporate it, a month before it is to be used, with one-third part of leaf or vegetable earth and old decayed dung, and again dig this mixed earth two or three times. But if the soil produced from four or five year-old couch-grass roots, harrowed from a field of sound loam, can be procured, it is the best aliment for the cucumber. The soil should be ready in April, and the work of planting begun in the first week of May, by filling the excavation with stable manure to the height of a foot above the surface-level of the unmoved earth, and placing on it the frame and lights. In a week, the manure will have settled, and is then to be covered with a six-inch layer of the couch-mould or other soil, and a hill of dryish earth, raised a few inches higher, under each light, in which eight or ten seeds of any approved variety may be sown. If preferred, the seeds may be prepared by previous sowing, in pots in a slight hotbed, and the plants so raised can be transferred to the hills. But as the plan now recommended is not one of forcing, it is safer to begin on the spot by sowing seed and covering the bed with the lights, and those with mats or boards every night.

As the plants rise, observe them carefully, and pick out the central buds when the true leaves have become strong. 'When the plants shoot forth after a second stopping above the second joint of the laterals, produced by the first, they seldom miss to shew fruit at every joint, and also a tendril, and between this tendril and the shewing fruit there may be clearly seen the rudiment of another shoot. This shoot is then in embryo, but if developed, it becomes a fruitful lateral. And when the leading shoot has extended itself fairly past the shewing fruit, then with the finger and thumb pinch it and the tendril off just before the shewing fruit, being careful that, in pinching off the tendril and the shoot, the shewing fruit be not injured. This stopping of the leading shoot stops the juices of the plant, and enables the next shoot—the rudiment above mentioned—to push vigorously, and the fruit thereby also receives benefit.' (M'Phail.) These remarks will also apply to the melon, which, however, requires more heat and more careful attention. The cultivation of these plants is, in fact, frequently carried on together either in the same or in separate frames; and after the few remarks which

follow on forcing, nothing further need be said of the cultivation of melons.

Whether cucumber and melon plants have been raised separately in pots, or from seeds sown in the frame, they ought to be progressing early in June, and should be stopped occasionally, till fruit begin to shew itself. The soil must never be *wet*, but always retained in a free and rather moist condition, water being kept in the frame for the express purpose. No water ought to be poured against the stems—it should be applied to the soil around the slope of the hills only. Air ought to be admitted on all warm days, by tilting the back of the lights till three o'clock; but after that hour, the frame should be kept closed. When fruit is visible, stopping according to M'Phail's direction, should be persevered in, and its fertilising effects will soon be apparent. Cover with mats, and boards over them, at sunset. Every decayed leaf and weak shoot should be removed as soon as perceived.

In order to raise and fruit cucumbers or melons before midsummer, *forcing* must be employed. The hotbeds of the best regulated gardens are conducted without masses of manure under the roots; heat is obtained by means of hot-water tanks, thus manure is economised. By this method, cucumbers and melons can be produced during the spring and summer months with certainty and precision. In the cultivation of both these plants, equability of heat is important; and nothing would be more likely to secure this, and also to ward off sudden accession of cold, than to case the frame with an inner lining of thin boards, leaving a space of an inch or two between, to be filled with some imperfectly conducting substance, such as powdered charcoal or dry saw-dust, and taking care to secure it from the ingress of water. The expense would be trifling, and the security afforded very great.

Nasturtium, or Indian-cress (*Tropæolum majus*), is a native of South America, but is not tender. Although chiefly grown as an ornamental annual, the green seed-vessels are used as a pickle. These, when they ripen, separate and drop on the ground, where they remain torpid till the spring. It therefore requires no minute directions; and any one who once possesses a plant, can multiply it by sowing seed in any way or place which may suit his taste. It may be sown with safety from the middle of March to the middle of May.

Parsley.—Several kinds of parsley are in cultivation; these are the plain and curled-leaved, and the common and the broad-leaved, or Hamburg parsley. Preference ought to be given to the curled-leaved parsley. This vegetable is one of the most easily cultivated, and it will long keep the ground with little trouble. It is sown in drills—generally in March—in any spare patches of border, lies long in the ground before springing, and arrives at maturity the next season. When it has attained this state, it may be cut when required; even during a long winter-storm, if the precaution has been taken to cover a drill or two with peas-stakes or other close wattling. It should not be allowed to go to seed, but kept well cut down.

Rhubarb is a large vegetable, grown for the sake of its firm leaf-stalks. The leaves are very broad and spreading, to catch moisture, and shelter the ground around the main-stem from the exhausting heat of the sun. When once planted, it requires no trouble, but keeps growing till the plant runs up to seed. To give additional size to the stems, cut off the seed-stalk. Suckers taken from known and approved plants succeed well, but the plant can easily be raised from seed. Each plant requires considerable space; and in preparing a plantation of rhubarb, the soil should be thoroughly worked to a great depth. In taking away the stalks for use, do not cut them, but wrench them from the main stock, so as to take them out by the socket. The variety called Victoria Rhubarb is the one generally chosen as the best and most productive. Rhubarb may be forced by very simple means. A common method is to cover it in the early part of the year with a box, to which air is admitted, and covered with a little stable manure. This blanches as well as brings forward the stalks; but that is an advantage, as it renders the vegetable more tender and delicate in flavour. Some bring forward rhubarb in pots in darkened forcing-houses, and for this purpose plants two years old are most suitable. Watering copiously is necessary in the early stages of growth, whether in the open air or under boxes. As rhubarb forms a valuable vegetable for tarts in spring, before gooseberries are ready, it would not be misspent time or trouble for a cottager to attempt forcing by the simple means above recommended. A well-planted plot of rhubarb, according to Mr Paterson, will continue productive for seven years; but a new one should be made a year or two before removing the old, and in the meantime, some light crop may be raised on the new ground, which is but thinly occupied by the young plants.

Sea-kale is a perennial vegetable, deriving its name from being found growing in a wild state on the sandy downs which border the southern coasts of England. The method of garden culture is as follows: Beds or spaces for single rows should be trenched and prepared as for asparagus; and at any dry period of March, when the surface-earth will work freely, one or more drills should be drawn by the line, two inches deep, and the seeds scattered along the drill; or five or six seeds should be inserted at distances of two feet apart. The seeds are then covered with earth, and when the plants become strong, they are to be thinned of supernumeraries, leaving one or two of the strongest remaining, eighteen inches or two feet asunder every way. If the plants be weak, it will be prudent to retain double the number. During the first season, nothing more will be required than to keep the bed or row free of weeds. In the following spring, if the plants stand nearer to each other than eighteen inches, the surplus number should be carefully raised, and transferred to another prepared space, planting the crowns of the roots two inches below the surface. Eighteen inches to two feet, according to the strength of the plants, may be the regular distances at which they are to remain. The first bed, if pots be placed over the crowns, will yield a moderate supply of blanched kale during April or May of the second spring.

Sea-kale may be forced at various periods, commencing with November, by inverting large pots over the plants, and covering those with warm dung, or dung and leaves, to excite and maintain a heat in the pot and soil of about 55° Fahrenheit. Sea-kale, like other plants subjected to heat, can be made to conform to induced habits. Thus at first it seems to remain long torpid, even though the heat be considerable; but after a second season, provided the gardener be himself regular, the plants will yield to the stimulant almost to a day, though it be comparatively mild; hence sea-kale is at command from December to March by heat, and then the succession can be maintained during April and part of May by the cold beds or rows. 'You may have excellent sea-kale,' says the author of the *Manse Garden*, 'in April from drills ridged up with earth; in which case every pair of drills must have greater distance for the convenience of mounding, and the plants may be so much closer in the bed. Straw in contact with the plants is unsuitable to blanching, as it communicates a bad flavour; but raked leaves do well, perhaps fern, sand certainly. Where the plant grows wild, as it does by the sea-shore in several parts of England, it is gathered in the finest condition when whitened by the sand, which the wind piles gently over its head in the manner of a snow-wreath.' As soon as the kale is cut from one or more roots, a sharp spade should be thrust through it, so as to cut the plant level with the surface.

Spinach is an annual of which there are two principal kinds: the round-leaved, smooth-seeded, which is sown chiefly for spring and summer crops; the triangular-

leaved, prickly-seeded, or winter spinach. The round-leaved should be sown about the end of January, and again in February and March, for successive spring and summer crops. The triangular-leaved is to be sown at the end of July or first week of August, and the leaves come into use at the beginning of winter; the plants require thinning and hoeing, and may be transplanted. The outer leaves only are to be taken during winter and spring, the inner leaves forming in their turn an ample succession. The seed or flower-stalks will become apparent in the early part of the summer, and some of the best plants, male and female—for spinach produces both separately—should be left to perfect the seeds. Plants designed for seed should be thinned to the distance of eight or ten inches. Spinach may be raised in any common garden-soil; but the more that soil has been previously enriched with dung, the better; and for either winter or summer spinach, it is hardly possible to manure the ground too highly, for succulency adds greatly to the value of this vegetable. Liquid manure proves effective. Always select an open situation, not too near low-spreading trees, &c.; as in close and shady places it is mostly drawn up weak, and soon runs to seed, without attaining perfection. A kind of wild-spinach is not uncommon in Britain (*Chenopodium Bonus-Henricus*); but it is inferior in succulency to the garden sort, and more bitter.

Vegetable marrow is a species of gourd (*Cucurbita*), the pulp of which, from its richness and flavour, has been called *marrow*. It was brought originally from Persia, and was particularly noticed by Mr Sabine, in the *Horticultural Transactions*, vol. ii., where he described the best culinary variety as bearing a 'fruit of uniform pale-yellow or light-sulphur colour; when full grown, about nine inches in length, four inches in diameter, of an elliptic shape, the surface being rendered slightly uneven by irregular longitudinal ribs, the terminations of which uniting, form a projecting apex at the end of the fruit, which is very unusual in this tribe.' There are other varieties which produce fruit that weighs twenty or thirty pounds, oblong in figure, and quite green during growth; such fruit, however, is coarse in flavour, and in no respect equal to the small cream-coloured variety. Attention has recently been called by Professor Lindley to the probable benefits to be derived from the increased cultivation of vegetable marrows and other gourds (*Gardeners' Chronicle*, 1856), which have never been much prized in Britain.

Sow in pots of any light soil early in April, treating the plants exactly as cucumbers under glass. About the middle of May, transfer them to a bed of rich earth over a trench filled with warm stable-dung. Protect the plants by a hand-glass or frame, which, if the shoots are to run on the ground, should be raised by four or more bricks, giving air freely. When danger of frost ceases, remove the light or frame.

We have seen the best plants nailed and secured to a wall, as trees usually are. They bear profusely in summer and autumn, and are not subject to be injured by damp. The seeds are sown on the spot at the end of May, and one strong plant remains, being stopped once or twice at the tips of the advancing shoots, of which six are enough for each plant. It would be wise to place a large spare light or two sloping in front till midsummer, and again early in September. If it be desirable to save seed, preserve the fruit first formed on a plant reserved for the purpose.

Mushrooms.—We have great hesitation in saying anything of the artificial growth of this delicious vegetable, both on account of the difficulty which unprofessional gardeners labour under respecting the right sorts, and the complex methods which require to be employed for bringing forward crops. The greater number of mushrooms brought to market are of natural growth on old rich pastures; and it would appear that, without providing a similar kind of soil full of decaying matter, the plants cannot be raised. The method of procedure is very peculiar. The mushrooms are not sown in the form of seeds, for they have no observable seeds, but by spawn, or portions of their substance, mingled in the prepared soil. Mr Rogers describes the process of mushroom-culture as follows: 'In June or July take any quantity of fresh horse-droppings—the more dry and high fed the better—mixed with short litter, one-third of cow's dung, and a good portion of mould of a loamy nature; cement them well together, and mash the whole into a thin compost, and spread it on the floor of an open shed, to remain till it becomes firm enough to be formed into flat square bricks; which done, set them on an edge, and frequently turn them till half dry; then with a dibble make two or three holes in each brick, and insert in each hole a piece of good old spawn, about the size of a common walnut. The bricks should then be left till they are dry. This being completed, level the surface of a piece of ground, under cover, three feet wide, and of sufficient length to receive the bricks, on which lay a bottom of dry horse-dung, six inches thick; then form a pile, by placing the bricks in rows, one upon another, with the spawn-side uppermost, till the pile is three feet high; next cover it with a small portion of warm horse-dung, sufficient in quantity to diffuse a gentle glow of heat through the whole. When the spawn has spread itself through every part of the bricks, the process is ended, and the bricks may then be laid up in a dry place for use. Mushroom spawn, made according to this direction, will preserve its vegetative power many years if well dried before it is laid up; but if moist, it will grow and exhaust itself. The next subject to be treated of is the preparation of the dung for the bed; and for this purpose, none answers so well as that of the horse, when taken fresh from the stable, and without an admixture of straw, hay, or other litter.

'About Michaelmas is the general season for making mushroom-beds, though this may be done all the year round. A quantity of the dung mentioned should be collected, and thrown together in a heap to ferment and acquire heat; and as this heat generally proves too violent at first, it should, previously to making the bed, be reduced to a proper temperature by frequently turning it in the course of a fortnight or three weeks; which time it will most likely require for all the parts to get into an even state of fermentation. During the above time, should it be showery weather, the heap will require some sort of temporary protection, by covering it with litter or such-like, as too much wet would soon deaden its fermenting quality. The like caution should be attended to in making the bed, and after finishing it. As soon as it is observed that the fiery heat and rank steam of the dung are gone off, a dry and sheltered spot of ground should be chosen on which to make the bed. The place being determined on, a space should be marked out five feet broad, and the length—running north and south—should be according to the quantity of mushrooms likely to be required. If for a moderate family, a bed twelve or fourteen feet long will be found—if it takes well—to produce a good supply of mushrooms for some months, provided proper attention be paid to the covering.

'On the space marked for making the bed, a trench should be thrown out, about six inches deep; the mould may be laid regularly at the side, and if good, it will do for earthing the bed hereafter; otherwise, if brought from a distance, that of a more loamy than a sandy nature will be best. Either in the trench, or upon the surface, there should be laid about four inches of good dung, not too short, for forming the bottom of the bed; then lay on the prepared dung a few inches thick regularly over the surface, beating it as regularly down with the fork; continue thus, gradually drawing in the sides to the height of five feet, until it narrows to the top like the ridge of a house. In that state it may

remain for ten days or a fortnight, during which time the heat should be examined towards the middle of the bed, by thrusting some small sharp sticks down in three or four places; and when found of a gentle heat—not hot—the bed may be spawned, for which purpose the spawn bricks should be broken regularly into pieces about an inch and a half or two inches square, beginning within six inches of the bottom of the bed, and in lines about eight inches apart; the same distance will also do for the pieces of spawn, which, in a dung-ridge, are best put in by one hand, raising the dung up a few inches, whilst with the other the spawn can be laid in and covered at the same time. After spawning the bed, if it is found to be in that regular state of heat before mentioned, it may be earthed. After the surface is levelled with the back of the spade, there should be laid on two inches of mould—that out of the trench, if dry and good, will do. After having been laid on, it is to be beaten closely together, and when the whole is finished, the bed must be covered about a foot thick with good oat-straw, over which should be laid mats, for the double purpose of keeping the bed dry and of securing the covering from being blown off. In the course of two or three days, the bed should be examined; and if it is considered that the heat is likely to increase, the covering must be diminished for a few days, which is better than taking it entirely off. In about a month or five weeks—but frequently within the former time, if the bed is in a high state of cultivation—mushrooms will most likely make their appearance, and in the course of eight-and-forty hours afterwards they will have grown to a sufficient size for use; in which case the author recommends that, instead of cutting them off close to the ground, they be drawn out with a gentle twist—the gatherer filling up the cavity with a little fine mould, gently pressed in level with the bed.'

The method above described is intended for open-air culture; but in large gardens, a mushroom-house is usually chosen, the beds being formed in large shallow boxes, arranged in the manner of shelves around the walls. Light is not required; and mushrooms may be abundantly produced in a dark cellar or outhouse, provided suitable materials are obtained, and care bestowed in regulating the temperature and maintaining a moist atmosphere. About two years ago, Lord Murray introduced the system of growing mushrooms in sunlight, and the experiments with his mushroom-house in the Experimental Garden, Edinburgh, shew that this method is an excellent one.

HORTICULTURAL MONTHLY CALENDAR.

Having in almost every instance mentioned the seasons for sowing, planting, transplanting, and otherwise attending to the culture of vegetables in the kitchen-garden, it would only be waste of room to repeat directions, as is usually done, in connection with the different months. It is hoped, therefore, that the following general references to the months will be sufficient:

January.—Trench and delve up all open grounds, if the weather permit; and in warm exposures, sow early peas and other articles that are to be brought forward early.

February.—Continue turning up the ground designed for early crops; sowing may go on a little more briskly, especially in warm and well-sheltered borders.

March.—This is a particularly busy month, being, from its open and drying character, favourable for all works of preparation. Peas, beans, asparagus, onions, carrots, &c., are sown; and various articles are transplanted from frames.

April.—A continuance of preparing, sowing, and planting; hoeing, thinning, and clearing out of weeds require also to be attended to. In very dry weather, seedling-beds should be carefully watered.

May.—The main crops are now to be sown, early peas earthed up and staked, and young plants transplanted.

June.—Sow kidney-beans, runners, &c.; water growing plants, if required; hoe potatoes, cabbages, and peas; and thin out beds. Gather medicinal and sweet herbs, when in bloom, and dry in the shade for winter use.

July.—Sow broccoli for the last time; also turnips, lettuces, &c.; and prepare all the unoccupied plots of ground for autumn and winter crops.

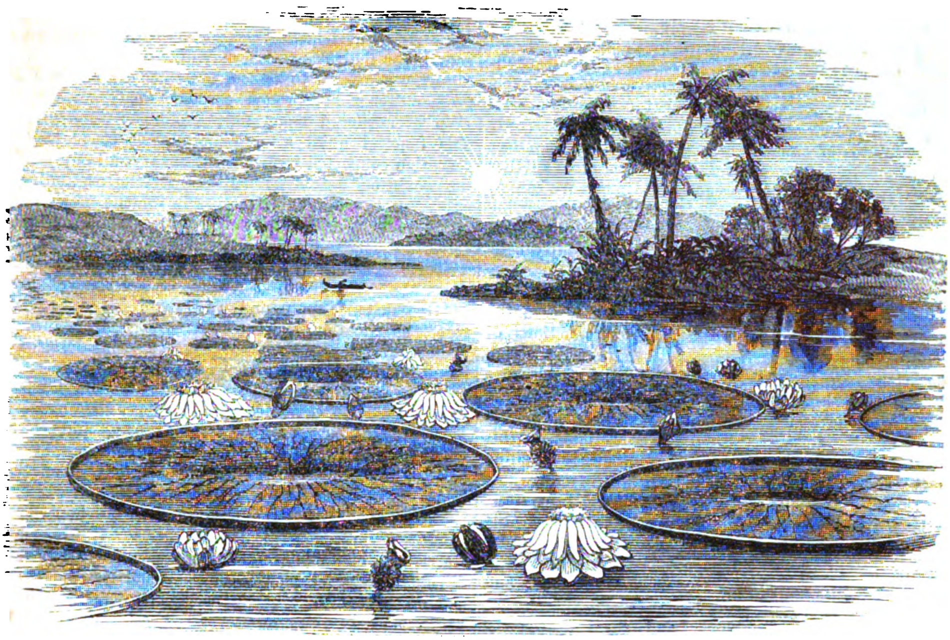
August.—Commence now to sow for the crops of next year, such as onions, early cabbages, and parsley; also winter spinach. Earth celery; hoe and thin turnips; cut down stems of gathered artichokes, and generally clear out all stumps and stalks of used plants, for their continuance exhausts the ground to no proper purpose. Cut herbs and gather all bulbous crops, such as onions, as soon as they are withered in the stem.

September.—The kitchen-gardener has now got his principal labours in cropping over, and his chief work is continuing to sow for winter and spring successions; he also digs potatoes that seem ready, and takes care to cut down and clear off weeds.

October.—The garden having been prepared for spring vegetables, sow what was left over last month, including celery, asparagus, also early peas and beans. The cabbages and savoys require to be earthed up as high as the leaves. Remove carrots and other roots, and store them away for winter use.

November.—If temperate and open, a little sowing may be continued in sheltered borders; but frost usually sets in early in the month, and puts a stop to cropping operations.

December.—During the latter end of November, and the open period of this month, the chief operations are digging, manuring, or trenching vacant ground, and attending to the preparation of composts. In frost, the labour exerted on the plants need only be protective; and the gardener usually occupies much of this period in pruning his trees, and attending to the more delicate plants in frames and sheltered borders. In mild weather, a few early peas and radishes may be sown in dry warm borders, and small salads and cucumbers in hotbeds.



Royal Water-lily (*Victoria regia*).

THE FLOWER-GARDEN.

FLOWERS have in all ages been cultivated by persons of leisure and taste, for the beauty and variety of their forms, colours, and fragrance. While generally healthful and exhilarating, from being pursued in the open air, flower-culture is justly reckoned a pure and harmless recreation, which, by leading to the tranquil contemplation of natural beauty, and diverting the mind from gross worldly occupations, has a positively moral, and therefore highly beneficial tendency. It often serves to awaken in previously listless minds a spirit of inquiry respecting the great phenomena of nature and the laws of vitality, which so vividly exemplify the wisdom, and power, and goodness of the Creator. It is therefore available as a useful auxiliary of education, as a stepping-stone to science, and as a means of elevating the moral character of a people, and their religious emotions. In ornamental art, too, all great designers have derived valuable aid from the vegetable kingdom: the lotus of Egyptian ornament, the honeysuckle and acanthus of the classic sculptors, are all *flowers* of architectural history; and in our own day, we find our most successful designers not merely copying the models of masters, but rather adopting their manner, and going back to nature as the direct source of their inspirations. Flower-gardening affords the ready means of studying vegetable forms, which, were they to be sought in the fields and woods, would necessitate a course of botanical study which few artists have the leisure or inclination to adopt. It has also the advantage of being alike open to the pursuit of high and low, the peasant and the peer, the overtoiled man of business and the industrious artisan. It may be followed with equal enjoyment by both sexes, and, as is well known, on every imaginable scale, from that of a single flower-pot or tiny front-plot, to the princely conservatory and exquisitely varied parterre.

The natural grace, simplicity, and attractive colouring of flowers have afforded endless themes to moralists and poets; and volumes have been penned to shew how many associations of feeling, simple and sublime, these beauteous subjects are calculated to excite. As our desire is to improve the feelings as well as to instruct the understanding, we hope to escape censure for pausing an instant over this agreeable view of the importance of floriculture, and would refer, for one of the most glowing eulogies on the subject, to the elegant work of Miss Sarah Stickney—the *Poetry of Life*. According to the well-expressed sentiments of this lady, few natural objects are more poetical, or more calculated to refine the taste, than flowers. 'From the majestic sunflower, towering above her sisters of the garden, and faithfully turning to welcome the god of day, to the little humble and well-known weed that is said to close its crimson eye before impending showers, there is scarcely a flower which may not from its loveliness, its perfume, its natural situation, or its classical association, be considered highly poetical.

'As the welcome messenger of spring, the snow-drop claims our first regard, and countless are the lays in which the praises of this little modest flower are sung. The contrast it presents of green and white—ever the most pleasing of contrasts to the human eye—may be one reason why mankind agree in their admiration of its simple beauties; but a far more powerful reason is the delightful association by which it is connected with the idea of returning spring. Perhaps we have thought long of the melting of the snow that impeded our noon-

day walk. But it vanishes at last; and there, beneath its white coverlet, lies the delicate snow-drop, so pure and pale, so true an emblem of hope, and trust, and confidence, that it might teach a lesson to the desponding, and shew the useless and inactive how invaluable are the stirrings of that energy that can work out its purpose in secret, and under oppression, and be ready in the fulness of time to make that purpose manifest and complete. The snow-drop teaches also another lesson: it marks out the progress of time. We cannot behold it without being reminded that another spring has come, and immediately our thoughts recur to the events which have taken place since last its fairy bells were expanded.

'It is of little consequence what flower comes next under consideration. A few specimens will serve the purpose of proving that these lovely productions of nature are, in their general associations, highly poetical. The primrose is one upon which we dwell with pleasure proportioned to our taste for rural scenery, and the estimate we have previously formed of the advantages of a peaceful and secluded life. In connection with this flower, imagination pictures a thatched cottage standing on the slope of the hill, and a little woody dell, whose green banks are spangled all over with yellow stars, while a troop of rosy children are gamboling on the same bank, gathering the flowers, as we used to gather them ourselves, before the toils and struggles of mortal conflict had worn us down to what we are now, and thus presenting to the mind the combined ideas of natural enjoyment, innocence, and rural peace—the more vivid, because we can remember the time when something like this was mingled with the cup of which we drank—the more touching, because we doubt whether, if such pure drops were still there, they would not to our taste have lost their sweetness.

'The violet, while it pleases by its modest, retiring beauty, possesses the additional charm of the most exquisite of all perfumes, which, inhaled with the pure and invigorating breezes of spring, always brings back in remembrance a lively conception of that delightful season. Thus, in the language of poetry, "the violet-scented gale" is synonymous with those accumulated and sweetly blended gratifications which we derive from odours, flowers, and balmy breezes; and, above all, from the contemplation of renovated nature once more bursting forth into life, and beauty, and perfection. The jasmine also, with its dark-green leaves and little silver stars, saluting us with its delicious scent through the open casement, and impregnating the whole atmosphere of the garden with its sweetness, has been sung and celebrated by so many poets, that our associations are with their numbers rather than with any intrinsic quality in the flower itself. Indeed, whatever may have first established the rank of flowers in the poetical world, they have become to us like notes of music, passed on from lyre to lyre; and whenever a chord is thrilled with the harmony of song, these images present themselves, neither impaired in their beauty nor exhausted of their sweetness for having been the medium of poetic feeling since the world began.

'It is impossible to expend a moment's thought upon the lily, without recurring to that memorable passage—"Consider the lilies of the field, how they grow. They toil not; neither do they spin; and yet I say unto you, that Solomon in all his glory was not arrayed like one of these." From the little common flower called heart's-ease, we turn to those well-known lines of Shakspeare where the fairy king so beautifully describes the "little western flower." And the forget-me-not has a thousand associations tender and touching, but unfortunately, like many other sweet things, rude hands have almost robbed it of its charm. Who can behold the pale narcissus, standing by the silent brook, its stately form reflected in the glassy mirror, without losing himself in that most fanciful of all poetical conceptions, in which the graceful youth is described as gazing upon his own beauty, until he becomes lost in admiration, and finally enamoured of himself; while hopeless Echo sighs herself away into a sound, for the love which, having centered in such an object, was neither to be bought by her caresses nor won by her despair? Through gardens, fields, forests, and even over rugged mountains, we might wander on in this fanciful quest after remote ideas of pleasurable sensation connected with present beauty and enjoyment; nor would our search be fruitless, so long as the bosom of the earth afforded a receptacle for the germinating seed—so long as the gentle gales of summer continued to waft them from the parent stem—or so long as the welcome sun looked forth upon the ever-blooming garden of nature.

'One instance more, and we have done. The "lady rose," as poets have designated this queen of beauty, claims the latest though not the least consideration in speaking of the poetry of flowers. In the poetic world, the first honours have been awarded to the rose, for what reason, it is not easy to define, unless from its exquisite combination of perfume, form, and colour, which has entitled this sovereign of flowers in one country to be mated with the nightingale; in another, to be chosen, with the distinction of red and white, as the badge of two honourable and royal houses. It would be difficult to trace the supremacy of the rose to its origin; but mankind have so generally agreed in paying homage to her charms, that our associations in the present day are chiefly with the poetic strains in which they are celebrated. After all the pains that have been taken to procure, transplant, and propagate the rose, there is one kind perpetually blooming around us through the summer months, without the aid or interference of man, which seems to defy his art to introduce a rival to its own unparalleled beauty—the common wild-rose. Blooming in the sterile waste, this lovely flower is seen unfolding its fair leaves where there is no beauty to reflect its own, and thus calling back the heart of the weary traveller to thoughts of peace and joy—reminding him that the wilderness of human life, though rugged and barren to the discontented beholder, has also its sweet flowers, not the less welcome for being unlooked for, nor the less lovely for being cherished by a hand unseen.' To these elegantly expressed sentiments nothing need be added by the writer of these pages.

MODES OF LAYING OUT FLOWER-GARDENS—FRONT-PLOTS—BOWERS.

Flowers are cultivated in the borders and parterres of gardens of a mixed kind along with kitchen vegetables and fruits; and this may be said to be the general plan in those grounds of limited space belonging to persons of moderate means. Many, however, cultivate flowers in 'flower-gardens' exclusively appropriated to them, and also in isolated clumps for the decoration of lawns. The method of culture is the same in all cases, and therefore it is unnecessary to enter into particulars with reference to the various sizes and kinds of gardens in which flowers may be grown.

The directions given in the previous sheet on the laying out, shelter, and exposure of kitchen-gardens, apply also to flower-gardens. The soil should be rich and dry, the exposure full and uninterrupted towards the sun, so that a free air may play over the ground; and means should be at hand for procuring a plentiful supply of pure soft water for irrigation.

If the garden is seen from a parlour-window, as is often the case, the plan most agreeable is to lay out the foreground as a patch of well-shaven green, which is fresh both winter and summer; on its further side there may be a semicircular border; then a walk; and next parterres of such form and size as will suit the extent of the ground. If the garden contain kitchen vegetables, they should be out of sight of the windows of the

dwelling-house, or at least not brought ostentatiously forward. 'It is more difficult,' says the author of the *Florist's Manual*, 'than may at first appear, to plan, even upon a small scale, such a piece of ground; nor, perhaps, would any but an experienced scientific eye be aware of the difficulties to be encountered in the disposal of a few shaped borders interspersed with turf. The nicety consists in arranging the different parts so as to form a connected glow of colour; to effect which, it will be necessary to place the borders in such a manner that, when viewed from the windows of the house, or from the principal entrance into the garden, one border shall not intercept the beauties of another; nor, in avoiding that error, produce one still greater—that of vacancies betwixt the borders—forming small avenues, by which the whole is separated into broken parts, and the general effect lost. Another point to be attended to is, the just proportion of green turf, which, without nice observation, will be too much or too little for the colour with which it is blended; and, lastly, the breadth of the flower-borders should not be greater than what will place the plants within reach of the gardener's arm without the necessity of treading upon the soil, the mark of footsteps being a deformity wherever it appears among flowers.'

Whether all the flowers of a kind—such, for instance, as violets, hyacinths, &c.—should be cultivated together in beds, or interspersed and mingled with others, is a matter for taste to decide. Dr Neill judiciously observed, on the choice of flowers for borders: 'The plants are arranged in mingled flower-borders, partly according to their size, and partly according to their colour. The tallest are planted in the back part, those of middling size occupy the centre, and those of humble growth are placed in front. The beauty of a flower-border, when in bloom, depends very much on the tasteful disposition of the plants in regard to colour. By intermingling plants which grow in succession, the beauty of the border may be prolonged. In a botanic garden, the same plant cannot be repeated in the same border; but in the common flower-garden, a plant, if deemed ornamental, may be often repeated with the best effect; nothing can be finer, for example, than to see many plants of double scarlet lychnis, double sweet-william, or double purple jacobæa.' The practice of growing flowers in beds of one kind has of late years, however, become very prevalent, and has this advantage, that it gives bolder masses of colour, and enables the florist to cultivate in the open ground, and with the best effect, many tender plants that would be lost in a mixed border.

The Dutch, who are among the best flower-gardeners in the world, have lately begun to copy the English in ornamenting turf-lawns with plots of various kinds of flowers; but in all their large and regular gardens, they still dispose each kind of flowers by themselves. 'We ridicule this plan,' says Hogg, in his *Treatise on Flowers*, 'because it exhibits too great a sameness and formality; like a nosegay that is composed of one sort of flowers only, however sweet and beautiful they may be, they lose the power to please, because they want variety. It must undoubtedly be acknowledged, that a parterre, no matter in what form—whether circular or square, elliptical or oblong—where all the shrubs, plants, and flowers in it, like the flowers in a tastefully arranged bouquet, are variously disposed in neat and regulated order, is a delightful spectacle, and worthy of general imitation. Yet still, in some particular cases, I am disposed to copy the Dutchman; and I would have my bed of hyacinths distinct, my anemones, my ranunculuses, my pinks, my carnations distinct, and even my beds of hollyhocks, double blue violets, and dwarf larkspurs distinct, to say nothing of different sorts of roses. Independently of the less trouble you have in cultivating them when kept separate, you have beauty in masses, and you have likewise their fragrance and perfume so concentrated, that they are not lost in air, but powerfully inhaled when you approach them.'

As to front-plots in towns and suburbs, if they be limited to a few square yards, it will be better not to attempt the growth of flowers at all, but to lay them down in greensward, if it will grow, or clean gravel, with perhaps a variegated holly, box-tree, laurel, flowering currant, sweet-brier, rose, or some other hardy shrub, to enliven them. Nothing, however, can be more wretched than a few sickly plants struggling for a miserable existence amid the dust and smoke of a town; and a person of good taste will never attempt the growth of flowers unless he can command the requisite amount of air and sunshine. In laying out little front-plots of this description, circular, oval, oblong, and other simple forms should be preferred; for nothing looks more ridiculous than the imitation of labyrinths and intricate designs on so small a scale. A few plain forms, in keeping with the front of the building and size of the plot, may produce elegance; but intricate divisions, with lines of gravel between, scarcely broad enough for a human foot, are toyish and trifling in the extreme. A neat box-edging should always be preferred.

An error not uncommon in deciding what flowers shall be planted, is to select numbers merely for their rarity or novelty, without reference to what will be their appearance when in bloom; a plan that generally leads to disappointment. Unless for botanical illustration, make a choice of flowers on two principles—those which will be beautiful when in bloom, although common; and those which will bloom at the particular seasons required, to insure a succession of variegated beauty from spring to autumn.

Bowers and rustic seats often form a pleasant feature in connection with the flower-garden. The forms of these are so numerous, that there is ample scope for choice; but there is one mode of forming a bower so novel and natural in character, that it is deserving of special notice. 'It sometimes happens,' says a correspondent of the *Garden Companion*, 'when trees are cut down to a few inches from the ground, that they send up shoots all round the stump. These shoots grow to a greater or less height, according to circumstances, and are frequently a source of annoyance.' One mode of overcoming this evil, or rather of converting an object of annoyance into an object of utility and ornament, is illustrated by the accompanying sketches. Fig. 1 shews

Fig. 1.—Tree-stump preparing for a Bower.

the stump of a tree (ash), with the young branches grown up round it; and fig. 2 illustrates the fashion in which these branches may be made to form an elegant canopy to one of the most natural of rustic seats—the stump of the tree—which may, however, be provided with a soft cushion if required. The branches need simply be tied together by means of wire; and if a few plants of ivy and brier, with one or two of the more choice climbing-roses, are planted around the base,

the whole will soon become very compact and beautiful. The wires should not be tied tightly, lest they cut the

Fig. 2.—The same, more advanced.

branches in the course of time; and perhaps, for this reason, ordinary string-ties would be preferable.

CHARACTER AND TREATMENT OF FLOWERS.

The design of the flower-gardener is less to produce size and strength in his plants, than to cause them effectually to bloom: he wishes a fine corolla. It is proper, then, to mention, that whatever tends to give excessive vigour to the stems, will prevent the formation of flower-buds. Thus a too rich and moist soil, or recent manure, is injurious.

Flowering-plants are usually divided into the following kinds: *Annuals*—plants which require to be sown annually, as they live and bloom only one season. *Biennials*, which do not blossom till the second season after sowing, remain a certain time in perfection, and then die. They are produced by seed, but some of the finest double varieties are continued by cuttings. *Perennials* are plants which continue for many seasons to grow and blossom annually. The greater number of our fine flowers and fruits are exotics—plants of foreign origin, which have been introduced into this country. Many are suited to our climate, but others require to exist in greenhouses and hothouses, or under glass frames, for at least a part of the year, and to these the term exotic more specially applies. Asiatic plants are remarkable for their superior beauty; African plants for their thick and succulent leaves, as in the case of the *Cacti;* and the American plants for the length and smoothness of their leaves, and for a singularity in the shape of the flower and fruit. The flowers of European plants are but rarely showy. Plants indigenous to polar and mountainous regions are generally low, with small compressed leaves, but with flowers large in proportion. Plants indigenous to New Holland (or Australia) are distinguishable for small and dry leaves, that have often a shrivelled appearance. In Arabia, they are low and dwarfish; in the Archipelago, they are generally shrubby, and furnished with prickles; while in the Canary Islands, many plants, which in other countries are merely herbs, assume the stature of shrubs and trees.

The different kinds of plants generally cultivated for their blossoms are either *herbaceous*—having annual stems; or *shrubby*—having permanent ligneous or woody stems. A *deciduous* tree or shrub is one which sheds its leaves every winter, and reproduces them in spring. An *evergreen* is a shrub which retains its leaves during winter, but casts them in spring as the new buds come out.

The prevailing colours of flowers are yellow, orange, white, pink, scarlet, red, blue, purple; and many are variegated, or composed of different tints. Proper culture, with pure air and sunshine, increase the brilliancy of the tints, and give massiveness to the corollas. Plants of kindred species may likewise be improved by hybridising or crossing, the general principle of which is the artificial application of the pollen of one plant to another (see VEGETABLE PHYSIOLOGY, pp. 74–5 and 80). By this means, some of the most beautiful flowers have been originated. Soil and climate, however, are the great means of improvement. The changes effected on the daisy, the rose, and the violet, will here occur to remembrance, as striking instances of metamorphoses induced by culture and change of habitat. Speaking of the laws by which a change of colour is produced, Dr Lindley observes: 'A blue flower will change to white or red, but not to bright-yellow; a bright-yellow flower will become white or red, but never blue. Thus the hyacinth, of which the primitive colour is blue, produces abundance of white and red varieties, but nothing that can be compared to bright-yellow; the yellow hyacinths, as they are called, being a sort of pale yellow-ochre colour, verging to green. Again, the ranunculus, which is originally of an intense yellow, sports into scarlet, red, purple, and almost any colour but blue. White flowers, which have a tendency to produce red, will never sport to blue, although they will to yellow—the rose, for example, and the chrysanthemum. It is also probable that white flowers, with a tendency to produce blue, will not vary to yellow; but of this I have no instance at hand.'

Propagation.

Dividing the Root.—This is one of the most simple methods of propagation. The root of the growing plant is partially uncovered, and one or more portions are removed; the root is then covered up, and the detached parts transplanted in soft earth prepared to receive them. Nine-tenths of herbaceous perennials may be treated in this way.

Suckers.—These are young shoots thrown up from the roots of the main plant, round which they cluster. They may be removed by taking up along with them a part of the root, as in the preceding method. They should be removed in spring, after the plant has begun growing, and immediately planted out. If any flower-buds be developed on them, take them off, so as to give strength to the leaf and root-developing powers to the plant.

Layers.—Some plants send out layers or runners along the ground; these have joints at certain points, which have a tendency to take root, and become the centre of a new plant. Thus a running plant will speedily cover, as with a net-work, a large space of ground. Nothing is more easy than to propagate by causing the layers of some plants to take root. In the case of the carnation and pink, the young side-shoots called *grass* are selected for layering. The shoots are stripped of their lower leaves, and the stem is cut half through by an oblique slit near the base; it is then fixed to the ground, with a hooked stick or peg, and is covered slightly with mould, giving a little moisture. Roots will in general strike out in a few weeks; and at the end of the season, the plant is ready for being cut from its parent and transplanted.

Pipings.—Propagation by piping is an expeditious mode of raising young plants. 'Take off the upper and young part of each shoot close below a joint, with a sharp knife, cutting each off at the third joint, or little knob; and then cut the top leaves down pretty short, and take off the lower and discoloured ones. When you plant the pipings, let the earth be light and sandy, and recently loosened; dibble no hole, but gently thrust each piping half-way down into the soft earth, and fix it in the bed. Water them often, if the weather is dry, but moderately, just to keep them moist; and shade them from the hot sun in the day. If pipings are

covered with a hand-glass, they root sooner than those which are exposed. Piping is done in June and July; and the plants will be well rooted and fit to plant out in October.'

Cuttings are strong shoots cut from the parent stem or branch, and set in the ground. The cutting should be cut off slantingly and smoothly; and the soil requires to be dry, or not too moist. Roses and honeysuckles are among the shrubby plants usually propagated by cuttings; and familiar examples of more succulent ones are seen in geraniums, verbenas, petunias, fuchsias, calceolarias, &c.

Budding is a method of propagation chiefly used in connection with fruit-trees; but as it is likewise applicable to rose-bushes, it may here be described. It is a species of grafting, and consists in inserting the fresh-cut bud beneath the bark of another plant. A leaf-bud, easily known by its tapering point, should be alone selected, and not a bud in which a flower is developed. The leaf on the selected bud is to be taken off, for if it remained, it would exhaust the sap, and the bud would in all likelihood wither and die. Along with the bud, a small slip of bark is to be taken; and if this bark separate freely, it is a test of there being sap enough to form a union. The slip of bark is to be inserted beneath the bark of the other plant, in a slit made for the purpose, and the whole tied with a strip of mat or gutta-percha, to keep out the air. The subjoined cut

Fig. 3.

represents the various parts in budding: *a* is the bud cut out, with a shield of bark attached to it; *b*, the stem, with a slit in the bark to receive the shield attached to the bud; *c*, the bud inserted, and the leaf cut away.

SELECT FLOWERS FOR THE GARDEN.

Flowering plants are now so numerous, both as respects species and varieties, that a bare list of them would more than fill the present sheet. All, therefore, that can be reasonably expected from us is a few hints as to those which are most approved, and cultivated chiefly in the open air. A person with little experience should stock his garden only by degrees—adding a small number of different sorts every year, according to fancy, and what he finds to be the capabilities of the soil and exposure. In commencing to make a choice for a moderately sized garden, or for still smaller plots of ground and borders, we should also recommend the plan of cultivating a mixed variety of different colours and different heights—those which are smallest being in front, and nearest the eye, and the other rows rising in height and massiveness as they recede. With as few as four colours, four sizes, and six different periods of coming into bloom, a mingled border may be established with ninety-six sorts, which will present a pleasing assemblage to the eye.

Annuals.

Some annuals are called *hardy*, and others *half-hardy*. The hardy kinds will grow and blossom in open borders, without artificial heat or protection; those which are more tender will also grow in the open air, but are improved by being brought forward under hand-glasses. Of the delicate class of annuals which must be constantly kept under glass frames, it is not our purpose to speak. The greater number of annuals may be sown in the month of April. The soil should be fine, and have a warm exposure; and on being sown, cover the seeds only slightly with mould; peas and lupines should be an inch below the surface. If the weather be dry, irrigate with pure soft water occasionally.

Among the vast number of annuals that offer themselves to the choice of the gardener, the following, most having varieties as to colour, may be mentioned as taking the lead in the *half-hardy kinds:* African marigold, French marigold, China aster, marvel of Peru, sweet sultan, Indian pink, convolvulus, amaranthus, ten-week stock, &c. *Hardy kinds:* Adonis, candytuft, larkspur, lupines, sunflower, lavatera, poppy, nasturtium, sweet pea, Venus's looking-glass, Virginian stock, mignonette, purple jacobæa, Clarkias, Collinsias, Nemophila insignis, maculata, and many others.

If annuals are required on a more extended scale, the best plan is to leave the selection to a respectable nurseryman. Such a person will at least present a copious list to make your choice from, and mention the size or height to which the plants will respectively grow.

Whether tender or hardy, all annuals should be carefully trimmed, and kept from straggling. Some will require thinning. Preserve the strongest blossoms for seed; and remove withered and imperfect blooms, to add vigour to those which remain.

Biennials.

The difference between biennials and perennials is in many instances very ill defined. A biennial is said to be a plant which, when sown, does not bloom till the following summer, and dies out in the course of autumn. This is true as respects some biennials, but it is equally certain that many will survive and bloom year after year, the same as perennials. For instance, carnations are called biennials, although it is notorious that these plants will grow and multiply by roots in the same spot, year after year, with only ordinary culture.

Among biennial plants suitable for ordinary flower-gardens are included the following, each having several varieties: Canterbury bells, carnation, pink, hollyhock, sweet-william, wallflower, Lavatera arborea, purple digitalis, and stock gilliflower. Some of these are very beautiful, and none more so than carnations.

The *Carnation.*—There are many varieties of the carnation, but all are arranged in three classes—flakes, bizarres, and picotees. Flake carnations possess but two colours, with large stripes through the petals. Bizarres have three shades of colour, also in stripes. Picotees have a white or yellow ground, marked on the margins with purple or some other colour. Carnations should have a flower at least three inches in diameter, with the edges of the petals waving or smooth, not serrated. The petals must fill the calyx, but not to bursting; if a calyx burst, the flower has been imperfectly cultivated. 'The calyx,' says Hogg, 'should be at least one inch in length, terminating with broad points sufficiently strong to hold the narrow bases of the petals in a close and circular body. Whatever colours the flowers may be possessed of, they should be perfectly distinct, and disposed in long regular stripes, broadest at the edge of the lamina, and gradually becoming narrower as they approach the claw of the petal. Each petal should have a due proportion of white, one-half, or nearly so, which should be perfectly clear, and free from spots. Bizarres, or such as contain two colours upon a white ground, are esteemed rather preferable to flakes, which have but one, especially when their colours are remarkably rich and very regularly distributed. Scarlet, purple, and pink, are the three colours which predominate in the carnation. When the pink flake is very high in colour, it is customary to distinguish it by the appellation of rose flake.'

The following, which we copy from an agreeable

horticultural treatise, *The Manse Garden*, are the plainest directions we have seen respecting the culture of carnations: 'The best soil for carnations is good loam, enriched with well-rotted stable-dung, and quickened with a little sand. The quantity of manure can only be determined by the previous strength of the ground: if made too rich, the flowers will lose their fine colours; if left too poor, they will want vigour. No recent manure should ever come near a fine plant. Let the ground be prepared before winter with dung, and a rough furrow laid up to the frost. In April, give a fresh digging, and plant in rows three feet by two. This width is to make room for layers, without which a fine blow of carnations cannot be maintained above one year. As the plants shoot up, they must be tied to neat green rods; and in order to have a fine blow, superfluous flower-buds must be pinched off, leaving only three or four to each stem. The young shoots near the ground, which do not run to flower, are denominated grass; and from these the layers are selected. The operation is somewhat nice, but when rightly done, is always successful, and good flowers are thus preserved and multiplied from year to year. Towards the end of July, stir up the ground about the plants, and mix with the soil a little old well-wrought compost. Have at hand a sharp penknife, a trowel, and a number of small pegs with an angle at the head: pieces of fern will do, or wood of no more strength than to bear pushing into the ground. Scoop out the earth in the form of a basin around each plant; select the strongest grassy shoots for layers, and remove such as are in the way; crop the top leaves an inch from the heart, and pinch off all the rest, taking care not to peel the stem. Begin an incision on the under side of the shoot, a little below the second joint from the top, and cut upwards till the joint is slit in the middle. Set the pointed extremity made by the slit into the bottom of the excavation, and there fix it with the peg; place the head of the shoot erect, fill in the earth, make it firm, and finish the work with a good watering. The young plants will be ready for removal by the end of autumn, when they may be set in flower-pots if the soil is too damp, and apt to cause rotting in winter; but if sufficiently dry, the layers may remain till spring, and it will be of use before winter to earth them up, sloping and beating the mould about them so as to throw off the rain. Although the propagation of this plant by pipings—as the grass-shoots taken off and stuck in the ground are called—is by no means so sure as the above method, yet of a number some will take root; and as pipings are more easily procured than plants, the experiment may be made. If carried to some distance, steep the slips in water till they swell to their proper size; trim them as above directed, and set them firm into prepared soil; water plentifully, and set over them a hand-glass, first throwing water on the glass, and then earth to darken it, and let it not be stirred for some days, it being found that a deficiency both of light and air promotes the striking of slips—probably on this principle, that the sick, having no appetite, must avoid the exertion which requires food as well as that which food requires.' When fully grown, the flower-stems should be tied with a strip of bast to a small stake or green wire thrust into the ground at their side.

The *Hollyhock* is a splendid flowering plant, and exceeds all others in stature. With good soil, shelter, and proper exposure, it will attain a height of twelve or fourteen feet, and generally reaches seven or eight. It is a substantial herbaceous plant, with a thick stem, along which, to the top, are the broad showy blossoms; and from this attractive appearance it is very suitable to ornament fronts of cottages, edgings to shrubberies, or the centre of clumps in lawns. The colours are very various; as pink, dark purple, yellow, &c.—the double sorts being the richest and most esteemed. The seeds of hollyhocks are sown in May; and in September or October the young plants are transplanted into the ground where they are intended to blossom; but the improved varieties of this flower that have been brought into existence within the last few years, require to be propagated by cuttings alone. Although classed as biennials, the plants will spring and bloom for a number of years.

Wallflower.—There are several sorts of this fragrant plant, those flowers which are dark and most massive being most highly esteemed. Their perfume is very pleasing, and their culture no way troublesome. 'To insure a succession of the best breed—and the method applies to the double flowering, which yields no seed, and cannot otherwise be preserved—about the beginning of July pinch off slips or young shoots of five or six inches in length, taken only from the finest stocks; crop the leaves, and strip the rest of the stem bare; dibble the slips so prepared into a bed newly dug, and shaded by trees or a north wall. Sprinkle them with water, and shade any part to which the sun has access. Not one will go back; and in this way a profusion of one of the sweetest flowers, and the best of its kind, may be had from year to year.'

Perennials—Bulbs.

Under this head may be included the hyacinth, narcissus, iris, lily, tulip, snow-drop, crocus, and others.

The *Hyacinth* has a tapering bulb, shoots up long green leaves, and in the centre is a stalk on which the blooms, in the form of bells, grow all round, causing it to droop or bend. There are numerous varieties, differing in colour—as blue, red, and white. The hyacinth is a favourite of the Dutch, by whom it has, like the tulip, been brought to great perfection. A sandy soil and saline atmosphere, with a warm exposure, are favourable in developing its properties. In the British Islands, the hyacinth will endure the winter in the ground, and is among the earliest blossoming plants of spring. In Holland, the bulbs are lifted and carefully stored during winter. The grower who desires to meet with success, must obtain an annual supply of Dutch bulbs, which are to be had from the seedsmen. The domestic culture of this flower will be alluded to under another head.

Of the *Narcissus* there are many varieties, which include daffodils, white narcissus, jonquils, and polyanthus narcissus. Most have a lightish-yellow flower, with a deeper yellow cup. A fine narcissus has tall and firm leaves, and from the centre springs the round tube-like flower-stalk, on the top of which is the bright-yellow bloom, with petals spreading out like the rays of a star: the criterion of excellence is massiveness and distinctness of colour in the corolla. Of the polyanthus species there are at least a hundred sorts, sulphur-coloured, single and double, white, &c. Like hyacinths, the bulbs may remain in the ground during winter.

Of the *Iris* there are various sorts, all of them beautiful from the delicacy of colour. The Persian iris is low, with delicate blue and violet blossoms; the Chalcedonian is taller, and distinguished by the great size and magnificence of its flower, which is a purple-blue striped with white; the English is of still greater height, and has flowers of large size. None require much sun.

The *Lily* is a plant equally tall with the larger iris. There are many species, with different colours—white, orange, and carmine. The orange, speckled with dark dots, is the more common. This plant will grow and bloom with little sun, or under the shade of trees. The effect of the orange-coloured blossom is pleasing among green plants which require to be set off by a contrast. The Japan lilies, not long since introduced to flower-gardening, are found to be most valuable ornamental plants, whether they be treated as exotics, or as hardy herbaceous plants. *Lilium giganteum* is also a striking addition to our lists, from India.

The *Tulip* is the pride of the garden, or at least stands pre-eminent in general estimation. Like many other bulbs, it is a native of the Levant, and was brought to its perfection in Holland, where tulip-fancying was at one period a mania, and the bulb is still a large article of trade. The finest tulip-gardens are at Haarlem, which has a warm and saline climate, with a soil light and rich. Round the roots and over the beds, sand is freely scattered, so that the tulips seem as if growing from a sandy beach. In planting in this country, follow the same practice. Plant in October, or early in November. In forming a bed of tulips, the bulbs should be set at a distance of seven inches apart, and in straight rows, taking care to mix the different colours. To raise from seed, or to improve the varieties by crossing, is a work of time, and not to be thought of in ordinary circumstances. The following is Hogg's criterion of a fine variegated late tulip: 'The stem should be strong, elastic, and erect, and about thirty inches above the surface of the bed. The flower should be large, and composed of six petals: these should proceed a little horizontally at first, and then turn upwards, forming almost a perfect cup with a round bottom, rather widest at the top. The three exterior petals should be rather larger than the three interior ones, and broader at their base: all the petals should have perfectly entire edges, free from notch or serrature; the top of each should be broad and well rounded; the ground colour of the flower, at the bottom of the cup, should be clear white or yellow; and the various rich-coloured stripes, which are the principal ornament of a fine tulip, should be regular, bold, and distinct on the margin, and terminate in fine broken points, elegantly feathered or pencilled. The centre of each leaf or petal should contain one or more bold blotches or stripes, intermixed with small portions of the original or breeder colour, abruptly broken into many irregular obtuse points. Some florists are of opinion that the central stripes or blotches do not contribute to the beauty and elegance of the tulip, unless confined to a narrow stripe exactly down the centre, and that they should be perfectly free from any remains of the original or breeder colour. It is certain that such appear very beautiful and delicate, especially when they have a regular narrow feathering at the edge; but the greatest connoisseurs in this flower unanimously agree that it denotes superior merit when the tulip abounds with rich colouring, distributed in a distinct and regular manner throughout the flower, except in the bottom of the cup, which should be a clear bright white or yellow, free from stain or tinge, in order to constitute a perfect flower.'

In order to have tulips in anything like perfection, they require great care. As strong sunshine injures them, they must be covered with a slight awning from the sun's rays. They must also on no account be allowed to go to seed, for in that case the bulb is exhausted; to prevent which, they should be watched when they approach perfection, and the head and stalk cut off. A usual signal for cutting is when they cease closing at sunset, or when the edges of the petals exhibit the slightest appearance of withering. They should be cut rather too early than too late. After cutting, admit the sun to the stems; and when these wither, which may be in June or July, lift the bulbs, and lay them aside in a dry airy situation; there let them remain till the period for planting, which is the end of October or beginning of November.

The *Crocus* and the *Snow-drop* are two small bulbous plants, so well known for their hardy growth, that little need be said of them. Crocuses are very various in colour—blue, yellow, white, and so forth; and the principal thing in planting is to dispose these colours in a pleasing variety. Crocuses, like other bulbs, require occasional transplanting: this may be done in October. Of the snow-drop, there is a double-flowered variety; and another species (*Galanthus plicatus*), the Crimean snow-drop, was brought into notice during the Russian war.

Perennials—Tubers.

In this group, the *Dahlia* (named from Dahl, a Swedish botanist), both from its beauty and size, deserves the first place. It is a native of the temperate plains of South America, and requires a dry and airy situation for its growth. The tubers at the root resemble long potatoes, and as they spread to some distance, the plant should have a free space of from two to three feet all round. The stems, at and near the top of which are the rose-like blossoms, rise to a height of four feet or more, and require to be supported by stakes. A new plant may be procured by separating a part of the root, to which a stem is attached. Frost at once blights the green stalks; and when these seem utterly withered and dried, carefully lift the tubers, and place them in a dry situation for the winter. In April, or early in May, they must be sprung on old manure under a glass frame, and then planted out, and occasionally watered. Dahlias are now found of almost every shade of colour, except blue, every year adding its novelty.

The *Ranunculus* is a stock beauty in all gardens, and it has some hundreds of varieties. The tubers are small. The blossom resembles a compact small rose of a flattish form. The soil in which the plants are placed requires to be fine and in good heart. In planting ranunculuses and dahlias, the colours should be arranged so as to produce an agreeable variety.

Fibrous-rooted Perennials.
